HE AUGURIES, SIGNS, ANL PORTENTS OF SURGERY*

234

Sir Cecil Wakeley
3.E., C.B., D.Sc., P R.C.S., F.A.C.S., F.R.A.C.S., F.R.S.E.
IOR SURGEON AND DIRECTOR OF SURGICAL STUDIES, KING'S.
LEGE HOSPITAL, LONDON; SURGEON TO THE ROYAL
IONIC HOSPITAL AND BELGRAVE HOSPITAL FOR CHILDREN;
CONSULTING SURGEON TO THE ROYAL NAVY

N this scientific age we must remember that the
ient is a human being and not a machine. Most
ients are anxious, and some are pent up and will
ll on every word the doctor says. The doctor there-
l should not be obscure and should not talk over the
ient's head—he should not be verbose and yet he
uld not be silent.

t is most important to secure the confidence of your
ent from the very outset; for having gained his
fidence you will be able to get a history of his com-
nt in his own words, and that history is more likely
e truthful. Confidence is important in any profession
onfidence in one's lawyer, parson, chauffeur, banker,
ilot—and trust in the doctor is a great asset to the
ent. Therefore get the confidence of your patient,
'e you are obtaining all the relevant data concerning
disease or injury, before you commence the clinical
nination. It may well be that the patient's relatives
be able to fill in some important gaps in the case-
ory. If they are available make use of their know-
e of the make-up and past history of the patient.
iable information may be forthcoming from this
ce which is nowadays so often neglected or spurned.
hen confidence has been obtained let us approach
patient determined to make our diagnosis before we
nit him or her to endless biochemical, metabolic,
ological, and instrumental investigations. Though
e investigations can certainly be helpful they are
ous and fatiguing to the patient; moreover they are
etimes misleading and may result in irreparable
age from delay. They should be used, as required,
onfirming a diagnosis, but not for making one.

some hospitals, as soon as a patient is admitted
ward, the resident medical officer, after a cursory
tion about his complaints, immediately orders
merable tests—pathological, biochemical, radio-
hical, and many others. No clinical examination is
e until the results of these tests are forthcoming,
then the clinical examination is not a thorough
because the results of the investigations have
idy biased the examiner. In some hospitals I have
ed, cases of suspected fracture are not seen by the
eon until an X-ray film has been taken; so the
nosis is made on the X-ray film and not on clinical
nination. There is a great danger of a Machine Age
iagnosis.

ow often has a surgeon removed an acute gangrenous
ndix from a patient, to be told afterwards that the
nosis could not be made because a barium meal a
th previously had revealed a normal appendix.
ice when I removed a gangrenous gall-bladder caused
orsion of its abnormal mesentery, the practitioner
harge of the case was much annoyed, because, he
the patient's cholecystogram had been normal in
y respect three weeks before the operation. But a
bladder possessing a mesentery is consistent with
rmal cholecystogram. [illegible]s has
e various manifestations of dise[illegible] distributions
eciated to the full by careful [illegible]mple the colics have
cal examinations. Do not [illegible]endicitis often starts with

doctors first and technicians last. Disease manifests itself in many ways. Let us train ourselves to interpret the various auguries, signs, and portents which are always to be found by the observant clinician. Let not the days of clinical acumen be numbered.

Voltaire once said: "A physician is a person who pours drugs of which he knows little into a body of which he knows less." Let us see to it that modern medicine has advanced since the time of Voltaire.

AUGURY

The art of augury or divination is no new one, and it has not always been a creditable one. Certain events were thought to indicate certain sequelæ. Certain combinations of events were thought to presage other events.

What of augury in surgery? When you begin your clinical studies you are perhaps at a loss when first you examine the patients. In the years of training you labour through the full examination of the respiratory system, cardiovascular system, locomotor system, and so on. You have taken a full history of the patient's complaints—his past illnesses, his habits in life, his age. As time passes you have laboured well, and certain combinations of history, age, and appearance have become for you auguries of disease. It is always well to consider whether or no the patient looks his age, and try to discover as much as possible about his habits before you ask direct questions. By so doing you can usually determine whether you are getting the whole truth from him. It is rarely necessary to ask a patient how many cigarettes he smokes a day; you can usually tell by noticing the colour of his fingers.

There are many examples of auguries of disease. To mention a few:

1. The fair fat fertile flatulent female of forty is indicative of gall-bladder disease.
2. The man over 50 years of age who rises from his bed at night, more and more frequently, to pass his water, suggests an enlarged prostate.
3. The patient over 40 years of age whose bowel habit changes may have a carcinoma of the colon.
4. The patient whose head is growing bigger may have Paget's disease.
5. The story of intussusception in children.
6. The change in type of the pain in chronic peptic ulcer may indicate malignant change in the ulcer.

To develop the use of auguries in surgery you must see as many cases as you can: for only by the comparison of cases, similar yet different (for all patients are different), can a combination of events become significant to you. When they have become significant you are in a strong position to pass forward to the interpretation of signs.

Some imagine that when they have seen one case of acute appendicitis all subsequent cases must or should be similar. But appendicitis is an affection which may appear in anyone at any time, though it is most common in young adults, and the male sex is more frequently attacked than the female. The disease may be of little significance, or it may occasionally run such a virulent course as to destroy life in a few hours. Its importance lies in the fact that it is an infective process, and, inasmuch as the peritoneal envelope is generally [illegible] to be said certain degree of peritonitis in almost modern times, for the young. How then [illegible] the common diseases in their early stages and not when the disease is so far advanced that the diagnosis is obvious.

The treatment of disease cannot be given until a correct diagnosis is made. Let the diagnosis be made on clinical grounds and confirmed by investigations in the laboratory or radiological departments.

Non potest medicus per epistulas eligere, vena tangenda est.

upon Tyne on Dec. 15, 1949

may not be evident except on rectal or vaginal examination, which should never be neglected. A definite swelling may sometimes be detected by palpation, usually above the outer half of Poupart's ligament, but varying in its position with the site of the appendix; it may be dull on percussion, but often it is tympanitic, since it consists of coils of intestine and omentum matted together around the appendix.

Cutaneous hyperæsthesia is manifest in more than half the cases of appendicitis. It is demonstrated either by stroking with a pin-point, held at right angles to the surface, or by light pinching. In the former, the two sides of the abdomen must be tested, as also the regions above and below the appendix area, which is usually contained within the triangle marked out by the middle line, Poupart's ligament, and a line drawn horizontally outwards from the umbilicus. In the pinch test corresponding portions of skin on the two sides of the abdomen are gently pinched between the thumb and finger, and the patient estimates the difference in sensation. The area of hyperæsthesia varies with different viscera, but it is uncommon to find it present in the absence of peritoneal inflammation. The appendix area corresponds in the main with the distribution of the 10th dorsal segment. Hyperæsthesia is better marked in young adolescents than in older patients, and may be exaggerated in hysterical or neurotic people. As the inflammation subsides, the area of hyperæsthesia gradually diminishes; its total disappearance without improvement of the general condition usually signifies grave mischief in the appendix, such as gangrene. I have stressed the importance of hyperæsthesia because it is often completely forgotten today.

Appendicular gastralgia is the name applied to cases in which all the signs and symptoms of the disease are referred to the epigastrium, and closely mimic those of a gastric or duodenal ulcer. The patients are usually women, and a test-meal examination reveals a hypersecretion of gastric juice, in which the hydrochloric acid is generally increased. Laparotomy shows no lesion in the stomach or duodenum, but chronic appendicitis is present. That the previous symptoms arose from the appendix is proved by the relief to the symptoms, and the changes in the gastric secretion, after appendicectomy. On the other hand, it must not be overlooked that a gastric or duodenal ulcer is often accompanied by pain referred to the right iliac fossa, and many an appendix has been removed without benefit to a patient with these conditions. The history of the case must be most thoroughly investigated. The pain of gastric or duodenal lesions is more persistent than the pain of appendicitis, and the intervals of freedom between attacks are shorter.

In appendicitis there is less vomiting, and it does not give the same relief as with duodenal lesions.

In a well-marked case the symptoms of appendicitis are so characteristic that the diagnosis is never in doubt. The pain, tenderness, fever, vomiting, constipation, abdominal rigidity, and perhaps swelling, form an almost unmistakable picture. The disease, however, often presents symptoms so varied, and manifestations so protean, that one is never surprised to meet it in all sorts of [illegible] settings. Human beings are not mass-[illegible] h one is different, and it is up to the [illegible] he differences in his several patients [illegible] t, the signs and symptoms

examiner in various final examinations up and d
land during the last thirty years I have been distressed to find that very few students and g use their powers of observation to the full; ve they miss the essential signs. There is a ten allow physical sloth to have the upper hand, a such important examinations as blood-pressure tions and the examination of the fundi are forgo

How often in a routine examination the doc to look at the finger-nails, the pupils, the neck, abdomen, or perform a rectal examination. Thi much may be found by a curious index finger, p used, in examining the rectum, the prostate, the vesicles, and the pelvis in women.

I well remember seeing a case of supposed cance rectum before the late war. The patient was a man of suffered from piles, and his doctor had ordered hi suppositories. Every night the patient had inserted pository, with its thin metal wrapping, into his rectu time came when he could not get another supposit and at this juncture he was sent to me. I removed positories, still in their tinfoil wrappings. Such remind us to be more definite and implicit in our to patients.

Piles in a middle-aged male are quite often the of a carcinoma of the rectum; and yet how o piles are treated and the cancer neglected. P the back may be caused by a secondary deposit i vertebræ from a carcinoma of the prostate; an how often the condition is missed for lack of a examination.

When eliciting signs use all your faculties:

Eyes.—Watch your patients' behaviour, gait, and hands; observe the colour of their skin, and their features for such disorders as early myxœdema.

Ears.—Listen to their speech; it may be rapid, lethargic, or aphasic, and any one of these may mean something which will help in the final di The presence of a cough may be significant, especially of the hawking variety so often heard in cases of pha pouch.

Smell may be of real use in some cases. For fœtor of the acute appendix patient, and the amm smell of the incontinent or the uræmic.

Touch.—The skin may be of the greatest help i cases. There is the moist hot hand of the thyrotoxic and the dry skin of the myxœdemic patient.

It is important that you relate your signs to pat by following your cases to the operation and by the operative findings and examining the patho specimens both macroscopically and microscop The post-mortem room may prove of real value in the value of certain signs and symptoms and in firming the diagnosis. The surgeons have a great a tage over their physician colleagues, for an ope will confirm or refute the surgeon's diagnosis, w the physician may have to wait for a post-m examination before his diagnosis can be confirmed

PORTENTS

The portents which give warning of something to happen, especially of a calamitous nature, are overlooked or forgotten.

The presence of blood in the vomit, sputum, fæc urine should always lead to further investigation.

Among portents, pain is one of the most com Bishop Westcott once wrote that pain was the ersal fact of life; and in my own experience e of the two commonest ity and its significance, we depend on our own s of sight, hearing, and touch. Therefore, in the ing of medical men and women, training in the eciation and interpretation of pain is of great rtance.

the first instance the doctor must differentiate een the pain due to stimulation of nerve-endings inflammation, infiltration by tumour, or by pressure tumour, distension, or derangements of normal tomy—and the pain which is due to unhappiness, ontent, or maladjustment to environment. This rentiation of organic from functional or psychogenic is all the more necessary because in a case of func- al or psychogenic pain prolonged investigations often ravate the condition. At the same time we must ember that psychogenic pain may well be as vivid disturbing to the patient as physical or organic n.

have already commented on the need for observation he patient while the history is being taken. The way atient tells his or her story; the account of the pain, nature, its anatomical extent, means of obtaining ef, or precipitating factors; the suggestibility of the ient—all these must be noted and appreciated.

hatever may be the doctor's reaction to the patient. to the history, let it be a guiding principle for us all elieve that a patient suffers pain if he says he does, and look therefore for symptoms and signs which are ly to confirm the story. Only by a process of exclusion we allow ourselves to arrive at the diagnosis of a ctional disorder. And even then the patient who is appy, discontented, or maladjusted, needs some p—if he will be helped.

hat are confirmatory signs of the presence and erity of pain?

1. *Nature of the Pain.*—Characteristic are the throbbing n of inflammation; the colicky pain of obstruction of ollow viscus or tube such as the cystic duct or the eter; the persistent dull ache of distension; the cinating pain due to direct involvement of a nerve- unk. And we must here determine how much the pain erferes with the patient's life—remembering at the me time how variable are the pain thresholds of different dividuals—a factor impossible of measurement and y estimable after long experience with many patients different conditions.

2. *Duration of the Pain.*—From the earliest times it s been stated that if pain is violent it is of short dura- on: and if it is long in duration it is moderate in verity. This is a truism, and merely reflects the working d resistance of the human organism. No patient puts with a severe pain for a long time. At the same time me of the most severe pains spontaneously disappear; rhaps to recur. The colics of obstruction of the biliary, imentary, and urinary tract are examples. These colics, hile they are present, are among the most severe that tients suffer. But often before the doctor arrives the tack has passed. Colic, the characteristic pain caused obstruction of the lumen of a hollow tube, is inter- ittent. But the pain due to inflammation is persistent; d the severity is often much less than that of colic. e all know the patient who has toothache, nurtures it r three days, and then calls in the doctor in the small urs of the morning.

3. *Distribution and Radiation of the Pain.*—Careful udy of patients suffering from various diseases has sulted in a knowledge of the typical pain distributions different conditions. For example the colics have haracteristic radiations: appendicitis often starts with entral abdominal pain which settles in the right iliac ssa: shoulder-tip pain is common in perforated peptic cer; and pain in the tip of penis in vesical calculus.

4. *Onset of the Pain.*—Familiar is the gradual onset of pain in cases of inflammation, in contrast with the *sudden* onset of pain in cases of perforation—so dramatic that the patient can usually state the time of onset, and say what he was doing—so dramatic that he stops in his tracks, so to speak.

We may add a word on the interpretation of pain in children. In infants more than in anyone else, the doctor must rely on the clinical picture—the findings of a complete examination and observation—in making his diagnosis. The parent's story must be well studied.

The nature of the vomiting is important: the projectile vomiting of the hypertrophic pyloric stenosis must be seen to be believed.

A simultaneous rise of pulse, respirations, and temperature some 48 hours after operation indicates collapse of the lung. The rising pulse of internal hæmorrhage following abdominal trauma, be it trivial or severe, should not be forgotten. And loss of consciousness after a latent period should be remembered as an indication of middle meningeal hæmorrhage.

It may be asked "Are there any portents of pleasant happenings?" I think not in surgery.

CONCLUSION

It is not recommended that all investigations should be dispensed with; but let it be remembered that a barium meal or a barium enema does not always show an ulcer or cancer, and a patient may be saved by exploratory laparotomy because the Auguries, Signs, and Portents have indicated it. Investigations take time, especially these days, and this time is saved if Auguries, Signs, and Portents are properly interpreted.

Equip yourselves to do so; put radiology, biochemistry, and hæmatology into their proper perspective and use them with judgment.

Are we teaching the men and women who qualify today to be good clinicians? I doubt it. They are hampered by an all too long and too complicated medical curriculum. The basic principles of medicine and surgery are not absorbed, because too little time is given to them: the various branches of general medicine and general surgery demand so much of the student's time that clinical medicine and surgery are perforce forgotten. Let us hope that when the new Medical Act is on the statute-book at Westminster, and every qualified person is required to do a year's postgraduate training before registration, clinical acumen will be considered an asset.

Let us hope that part of the year of postgraduate training will be taken in hospital or with a general practitioner, and that we shall thus revert to the former apprenticeship in medicine. It is the general practitioner who sees the early signs and symptoms; his mellowed clinical acumen stands him in good stead and he is able to act quickly. We all learn by experience, and often we are able to make a correct diagnosis in a difficult case, in which the signs and symptoms are conflicting, because we have seen identical cases before. During the early weeks of his internship the newly qualified doctor, in his keenness and inexperience, is inclined to be critical of the diagnosis of the general practitioner: but he gradually learns that the practitioner is usually right and that when an admission for an urgent case is desired it is better to admit than to refuse. There is a lot to be said for the apprentice system in these modern times, for the young doctor will see the common diseases in their early stages and not when the disease is so far advanced that the diagnosis is obvious.

The treatment of disease cannot be given until a correct diagnosis is made. Let the diagnosis be made on clinical grounds and confirmed by investigations in the laboratory or radiological departments.

PRIMARY UMBILICAL SEPSIS IN THE ADULT

REPORT OF SEVEN CASES

G. W. VAUSE GREIG
M.B. Leeds, F.R.C.S.
SURGICAL REGISTRAR

H. S. SHUCKSMITH
M.B., B.Sc. Leeds, F.R.C.S.
ASSISTANT SURGEON

THE GENERAL INFIRMARY AT LEEDS

FOUR examples of suppuration deep to the umbilicus in men, presenting with a purulent discharge from the umbilicus after a short period of abdominal pain, are described. In these cases the inflammation had spread intraparietally, and in one case intraperitoneally also. Three further examples, in women, where the inflammation caused only a purulent discharge from the umbilicus, are also recorded.

Primary umbilical sepsis is diagnosed mainly by exclusion, and this fact emphasises the importance of recognising the condition as a reality. When investigations of a case presenting with a discharge at the umbilicus have excluded as the cause the more common developmental abnormalities, primary peritonitis, tuberculosis of the parietes with the cold abscess pointing at the umbilicus, and inflammatory or neoplastic diseases of the stomach, gall-bladder, colon, or pelvic organs, the origin of the discharge from a local lesion in the umbilicus can be predicted with confidence.

The pathology of the umbilical sepsis was not recognised in case 1, and exploration of the umbilicus showed that the inflammation had spread intraperitoneally and was involving the anterior wall of the stomach. The consistence of the stomach wall was such that it simulated malignant disease, and a partial gastrectomy was done. Rintelen[1] records a similar experience with a man, aged 28, who presented with a discharge at the umbilicus after a fortnight's colicky abdominal pain. At operation a partial colectomy was done, since it was found that the retro-umbilical inflammation involved the transverse colon.

Primary sepsis at the umbilicus associated with inflammation in the abdominal wall has been variously explained by different writers. Cullen[2] described umbilical concretions with local inflammation in the abdominal wall, and in reviewing many cases previously published as tuberculosis, infected dermoids, &c., he considered most of them to be examples of primary umbilical sepsis. Trimingham and McDonald[3] in an article on congenital anomalies in the region of the umbilicus, point out that there are no sebaceous or sweat glands in the umbilicus and emphasise the importance and frequency of retro-umbilical dermoids as the basic cause of umbilical sepsis. In none of their cases, however, do they give a histological report which substantiates the presence of a dermoid, and their statement about the absence of sweat glands is incorrect.

CASE-RECORDS

Case 1.—A man, aged 33, had felt a nagging pain in the region of the umbilicus for five days. The pain got worse each evening and was accompanied by frequency of micturition; ultimately it became so severe that he collapsed. On examination a purulent discharge from the umbilicus was seen, and there was a tender swelling deep to the umbilicus which on compression produced more pus.

Operation.—On Aug. 14, 1948, the umbilicus was excised, and an abscess cavity containing fetid pus, reminiscent of the contents of a suppurating sebaceous cyst, was drained.

Special Investigations.—On culture of the pus a growth of diphtheroids, *Staph. albus*, and a non-hæmc streptococcus was obtained. A barium meal, a enema, and radiography of the lumbar spine and chest normal. Iodised oil injected into the sinus showed an i cavity not communicating with a viscus.

Second Operation.—On Sept. 9, 1948, a transverse enclosing the area of the umbilicus was made. The a cavity was found to extend intraperitoneally as far as anterior wall of the stomach; so the original incision enlarged by a vertical limb in the linea alba. An area of anterior wall of the stomach felt thickened and hard, a partial gastrectomy by the Billroth I method was d the duodenum being joined to the greater curvature of the stomach. The abdominal wound was closed with wire su

Convalescence was uneventful, with full recovery and to work.

Pathological Report (Prof. J. M. Stewart).—"To the na eye this medium-sized partial gastrectomy specimen sh an apparently neoplastic mass in the region of the ante wall and greater curvature. The main portion of the 'tumo is rounded in outline and measures about 5 cm. in diame Externally there is an adherent mass of fibro-adipose ti incorporated with the wall of the stomach. A diam shaped portion of the anterior abdominal wall 6 × 2 is firmly adherent to the pyloric portion of the stomach w a blind-ending fistulous track or sinus running inwards fi the skin surface.

"Histology: there is no evidence of neoplasm, the thicker of the stomach wall being due to inflammatory infiltra and œdema of the submucosa. The lesion lies in immed relation to the fistulous track observed by the naked and this track is lined by granulation tissue in which infl matory cells are present in large numbers, especially lymp cytes and polymorphs, with smaller numbers of eosinop and plasma cells. There is no evidence of a communicat between the sinus and the interior of the stomach, tho the muscular wall is penetrated for some distance and m disorganised by the inflammatory changes. The fun type mucosa covering the inflammatory mass shows w marked chronic gastritic changes with large and promin lymphoid nodules and much plasma-cell infiltration.

"Comment: the relation of the inflammatory lesion i fistulous track to the anterior wall of the stomach a from the lesser curvature makes it unlikely that the origi lesion was the result of gastric ulceration. The possibility its having originated in or near the umbilicus see likely."

Case 2.—A man, aged 35, had first felt abdominal sore on Aug. 21, 1948, after particularly heavy work. During subsequent week a stitch-like pain developed on both si of the umbilicus, and pain on micturition. The umbili itched and became red and swollen, and was incised by own doctor on Sept. 3. On his admission to hospital th weeks after the onset of symptoms, there was a profuse charge from the centre of an everted umbilicus, below wh was a tender swelling. A probe passed 5 cm. backwards downwards through the discharging sinus.

Operation.—The pouting everted lips of the umbilicus w excised, and the incision extended downwards through linea alba for 4 cm. The abscess cavity thus laid open situated between the peritoneum and transversalis fas It was about 3 cm. in diameter and contained a mass sebaceous-like material. The cavity healed in sixteen days.

Case 3.—A man, aged 53, had had a month's history stabbing pain in the right iliac fossa and a fortnight's hist of a purulent discharge from the umbilicus. Examinat revealed a discharging umbilicus and a swelling about 7 in diameter, below and partly to the right of the umbilic The mass was tender, and pressure caused increased fl of pus.

Operation.—Under general anæsthesia a radial incis from the umbilicus into the cavity was made, liberati stinking sebum-like material. The cavity was extraperiton but behind the abdominal muscles.

Convalescence was uneventful, the area healed in a mon and the patient returned to work.

Case 4.—A girl, aged 20, had noted at intervals o the preceding eighteen months a yellowish or bloodstain discharge from the umbilicus, particularly after exerti amination, before excision of the umbilicus, showed only ttle thin yellow discharge. Convalescence was uneventful.

---

[1] Rintelen, G. *Zbl. Chir.* 1937, 64, 615.

[2] Cullen, T. S. Embryology, Anatomy, and Diseases of the Umbilicus, together with Diseases of the Urachus. Philadelphia and London, 1916.

[3] Trimingham, H. L., McDonald, J. R. *Surg. Gynec. Obstet.* 1945, 80, 152.

athology.—Dr. T. Adler found, on histological examination, dence of low-grade inflammation of the skin of the bilical pit.

ase 5.—A woman, aged 22, had noted soreness and tation of the umbilicus a year ago, and since then an ermittent yellow purulent discharge from it. Examination wed that the umbilicus had a deep funnel-shaped depres- n, and there was tenderness in the right iliac fossa.

peration.—The umbilicus was excised, and convalescence s uneventful.

Pathological Report (Dr. T. Adler).—"To the naked eye e specimen of skin measures 7 × 4 cm. and is 5 cm. deep, th a navel in its centre. Section shows a rather elongated bilical depression with a small amount of reddish tissue neath the tip of the pit. Histological examination shows in from the umbilicus with slight cornification. Sweat nds are scanty, but their glandular portions are very large, d they can be found throughout the entire extent of the in of the pit, from which hair follicles and sebaceous glands e missing. The corium is infiltrated by round cells and some ollen histiocytes, more heavily towards and below the tip the umbilical depression. In this last site a small abscess d formed, surrounded by regional purulent lymphangitis. o obvious cause for this inflammation can be seen other than e accumulation of debris and the low-grade dermatitis within e navel itself."

Case 6.—A woman, aged 34, had had an intermittent ul-smelling purulent discharge from the umbilicus for four onths. Examination revealed no abnormality of the nbilicus or of the surrounding skin.

Operation.—The umbilicus was excised on June 2, 1949, d the wound had healed by June 10.

Pathological Report (Dr. T. Adler).—"Skin and sub- taneous tissue 12 × 5 × 3 cm. with central umbilicus. hough naked-eye examination shows no obvious abnormality, icroscopically there is an area of dense round-cell infiltration the cutis near the bottom of the navel pit. This infiltration most marked in the papillæ and forms dense sheaths round e spiral superficial portions of the sweat-gland ducts. The rresponding deeper duct segments and glands are normal, hich fact suggests that the inflammation has been caused by perficial maceration of the duct and epidermis epithelium ther than by retention of secretion and back pressure in the landular portions."

Case 7.—A man, aged 38, had noticed pain and tenderness und the umbilicus a fortnight before admission; this as followed a few days later by a thin yellow discharge. he pain and swelling increased and on admission he had an durated discoloured swelling extending about 6 cm. below nd laterally from the everted œdematous umbilicus g. 1). Pressure on the swelling produced a flow of pus rom the apex of the umbilicus. The inguinal glands were nlarged and tender. Dilatation of the orifice permitted the nsertion of iodised oil, and on screening there was seen to be large abscess cavity lying behind the abdominal wall but ot communicating with any intra-abdominal viscus. Only small sinus ran to the surface. Penicillin was given for three lays and many of the acute signs subsided though the ndurated mass remained.

Operation.—On Sept. 15, 1949, the umbilicus was excised and ound to contain a large plug of thick cheesy material. The abscess cavity was further opened by a vertical incision in the linea alba below the umbilical orifice. The deep wall of the abscess was then seen to be composed of greater omentum. The wound was partially closed with 'Nylon' sutures round a rubber drain to the cavity.

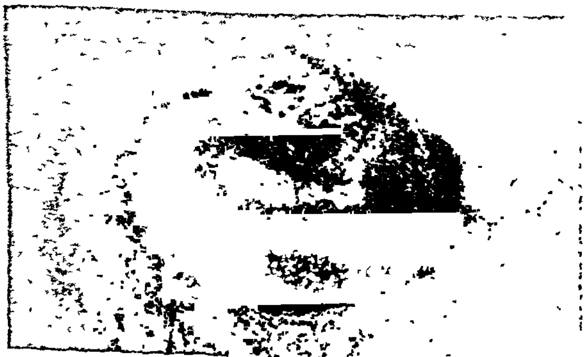

Fig. 1—Everted umbilicus (case 7)

The postoperative course was satisfactory and the man was discharged on Sept. 30, the wound then being healed.

DISCUSSION

Concretions and eczematous processes at the umbilicus are frequent in the aged, but the average age of our patients was 30. Cullen[2] states that primary umbilical sepsis is more common in men than in women, and that it occurs in the age-group 20–60 years. The illness begins with vague abdominal pain, localising later at the umbilicus, where a swelling appears. The umbilical opening becomes narrower, and the skin reddens: severe pain precedes the escape of pus. The margins of the umbilicus may be flat, or their place may be taken by granulation tissue, and the cavity deep to the umbilicus is filled with pus and stinking cheesy material which may contain felted hair or a concretion. Cullen considers that lack of cleanliness in a deep umbilicus leads to the accumulation of wool or hair from the clothes, and that this starts the inflammation, which narrows the external opening, the stenosis leading to the formation of an abscess; a concretion results when the pus becomes inspissated. Cullen reports 23 cases: 12 originally described as umbilical concretions, 5 as dermoid cysts, 2 as non-spreading tuberculosis, 3 as fistulæ, and 1 as a carcinoma. He believes that all are cases of primary umbilical sepsis.

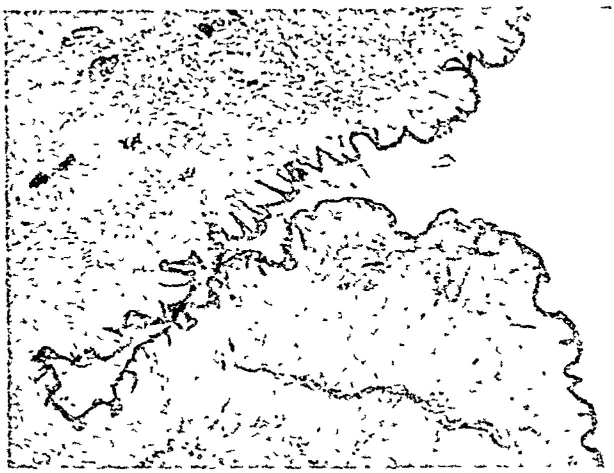

Fig. 2—Section of wall of umbilical pit, showing recess and sweat glands. (Hæmatoxylin and eosin, × 7.)

Hicken and Best[4] report 4 cases; in one the concretion ruptured intraperitoneally, and in another the history extended over six months, there being five attacks before the condition was recognised. These writers, unlike Cullen who advises simple drainage, consider that the condition will recur unless the umbilicus is excised, and they do not agree that lack of personal cleanliness is an ætiological factor. Enlarging on Cullen's suggestion that there is a narrowing of the opening, they postulate an accumulation of sebaceous material behind the stenosis, and that this sebaceous material forms a nidus for infection. The substance found in these abscesses is best compared with the contents of a suppurating sebaceous cyst, and an inspissated portion may or may not be present as a concretion.

As has been mentioned, Trimingham and McDonald[3] state that no sebaceous or sweat glands are found in the umbilicus. If this is so, doubt must be cast on the

---

suggestion that the abscesses result from stenosis of the umbilical orifice, necessitating serious consideration of a complication occurring in a developmental abnormality as the ætiological factor. Hicken and Best list the congenital anomalies which may be found at the umbilicus, of which the following conditions are pertinent to this discussion: alimentary-tract anomalies, such as a partially patent intermediate portion of omphalomesenteric duct (vitelline cyst); and urachal anomalies, such as a partially patent intermediate portion of the urachus (urachal cyst). They state that a vitelline cyst is lined with an intestinal type of mucosa, but that, as the cyst gets bigger, tension flattens the epithelium, and the original type of cell cannot be identified. Similarly, a urachal cyst may not show its original transitional epithelium. The fluid in these cysts they describe as like ascitic fluid or as containing ropy material or chocolate-coloured fluid resulting from previous slight hæmorrhages. If these cysts burst they do so at the umbilicus. The fact that epithelial characters may be lost as tension develops makes it difficult, on histological grounds, to be certain of the origin of some of these conditions, and much reliance may have to be placed on the presence of fascicles of smooth-muscle bundles.

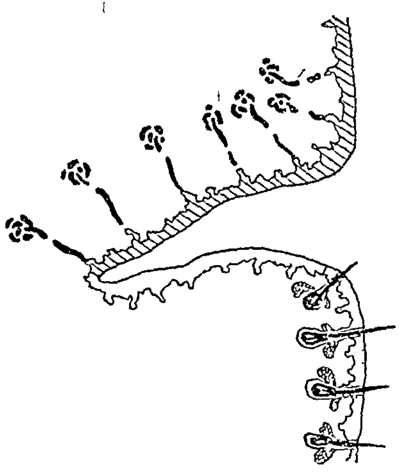

Fig. 3—Diagram to show distribution of sebaceous and sweat glands in umbilical pit: hatched, epidermis with sweat glands; stippled, epidermis with hair follicles and sebaceous glands.

Histological examination of the normal umbilical area by us refutes Trimingham and McDonald's assertion that neither sweat nor sebaceous glands are present in the umbilical skin. Dr. Adler gives similar findings in his pathological reports on cases 4, 5, and 6. All the sections show the presence of sweat glands throughout the umbilicus, but sebaceous glands present in the outermost part only of the umbilical pit (fig. 3). The sections also show many small recesses in the umbilical pit (fig. 2). Accumulation of keratinous debris in these recesses is an important mechanical factor leading to bacterial invasion, stenosis, and abscess formation in these cases, but the sweat glands may have considerable importance in determining the onset of sepsis and explain the development of the condition in spite of reasonable personal hygiene. Detailed histological examination shows lanugo hair follicles and sebaceous glands extending from the circum-umbilical, and particularly from the subumbilical, skin on to the inverted marginal rim of the umbilical pit. The walls of the pit have, as appendages, sweat glands of eccrine type which extend throughout the entire pit. The size of the secreting duct of the sweat gland varies considerably from person to person, and it seems, from evidence of round-cell infiltration round the duct but not round the deepest part of the gland, as in case 6, that the secretion of the sweat gland macerates the epithelial lining of the duct wall, and of the surface skin on to which it opens, with subsequent infection, stenosis, and abscess formation. No evidence has been found in this series that retention of secretion and retrograde infection of the glands play any part.

Case 1, in which the specimen obtained at operation was fully investigated by Prof. Stewart, showed no evidence of intestinal epithelium, and the progres the other cases after a simple operation inclines us to view that an accumulation of squames in the [illegible] recesses, depending in part on a dermatitis caused by sweat glands, is the basic ætiological factor.

We believe that the treatment, when an absces present, is simple drainage with wide efficient opening the cavity and removal of the contents, and [illegible] the umbilicus if no abscess is evident.

SUMMARY

Seven cases of primary umbilical sepsis in adults reported.

In one case, owing to lack of recognition of condition, the patient was subjected to pa gastrectomy.

The ætiological factors are discussed, and a mechani origin associated with the sweat glands in the umbilic is put forward as the likely cause.

Treatment in the first place should be by simple adequate drainage, or excision of the umbilicus if th is no abscess.

DIPHTHERIA IMMUNISATION IN YOUN BABIES

A STUDY OF SOME FACTORS INVOLVED

DURING the past three years we have been inves gating the quantity and rate of loss of maternally tra mitted diphtheria antitoxin in the newborn, how the passive antitoxin interferes with active response an injection of prophylactic, and the age at wh babies can respond efficiently to active immunisation.

The active immunisation of very young babies h also been investigated in Sweden by Vahlquist,[1] w showed that infants born without any passive antitox could be satisfactorily immunised with 1 ml. (45 of alum-precipitated toxoid at birth, though the antito response might be somewhat retarded. He also obtain evidence that a passive antitoxic concentration exceedi 0·1 unit per ml. interfered with active immunisation babies, whereas a concentration below 0·02 unit per did not.

Bousfield,[2] working with babies 3–5 months o found that of 43 children injected with one dose P.T.A.P. (25 Lf) 40 were Schick-negative at the age a year; with two doses of 12·5 Lf, given at an interv of a month, all of 51 babies were Schick-negative. each case the prophylactic was combined with pertuss vaccine. The tables in Bousfield's paper show, howeve that the three failures in the first group were all in babie under the age of 5 months; hence the Schick-negativ rate was actually 28 out of 31 (90·9%) in babies aged or 4 months, and 12 out of 12 (100%) in those age 5 months. The titres of passive antitoxin in these childre were not measured, and so the reason for the 3 failur is unknown; they may have been due to swamping-o of the antigen by circulating passively acquire antitoxin, or to the inadequacy of the single-injectio method.

We have previously given[3] figures showing that i two socially similar districts of South-East Londo 21 and 29 babies, from random samples of 100, wer with no detectable passively conferred antitoxin. the other hand, 6% from one of these districts and % from the other had 1 unit or more of antitoxin per ml. in their cord blood.

---

Any scheme laid down for the immunisation of young babies must take into account the immunity state and distribution of antitoxic values in the newborn. These may vary in different districts, and with the present widespread immunisation campaign the immunity state of the young adult population, including expectant mothers, may change.

Theoretical considerations suggest that much attention should be directed to the maintenance of antitoxin produced as a result of immunising injections, owing to the lack of subsequent stimulation from epidemics. If immunisation were general but slightly inadequate because of too small a dose, a state of affairs might arise in which the good responders reached and maintained relatively high levels of antitoxin, while the poor responders only reached low levels which were not maintained into adult life.

Whatever may be the effect of general immunisation, little is known about the amount of antitoxin present apart from the qualitative information obtained by Schick testing. This test, however, gives no indication of the levels of antitoxin in Schick-negative people, nor does the Schick-positive rate of a population give any indication of the range of antitoxic levels in the Schick-negative members of that population, there being no correlation between these two factors. Further, the Schick test may give a misleading impression of the general antitoxic levels if applied to babies at some definite chosen age—e.g., 3 months.

In a study of antitoxic levels in different districts, now being carried out by two of us with Dr. H. J. Parish and the help of a number of collaborators, we have found that, whereas in district A 42% of babies were born with antitoxic levels below the Schick level, the figure for district B was only 23%. The figures for the same babies at the age of 13 weeks would be A 61·8% and B 38·4%; and at 30 weeks 84·4% of babies in district A and 85·3% in district B would have fallen below the Schick level (we are taking the Schick level as being 0·002–0·004 unit per ml.). The figures given for 13 and 30 weeks were calculated from the formula derived from our earlier work, in which it was shown that the average rate of loss of maternally acquired antitoxin was represented by the equation $\log A_w = \log A_c - 0{\cdot}2 - 0{\cdot}065W$, where A_w is the antitoxic level of a baby w weeks old and A_c is the antitoxic level of the cord blood. Thus a Schick test done in the first few weeks of life, if this were practicable and reliable, would show great differences between these two populations, whereas a test dose at the age of just over 6 months would make them appear identical. We suggest that the distribution of antitoxic levels among infants should be followed by means of antitoxin titrations on a limited number of cord-blood samples, so as to determine the range of levels existing at birth and, by calculation, at any later age.

The ideal method for determining the best age at which to start immunisation would be to test the antitoxic level in the cord blood of every baby born, and to determine by the formula given above the approximate age at which the level would fall low enough not to interfere with active immunisation. Since this would prove too vast an undertaking, tests on a limited number of samples from different districts would give a good general picture of the immunity of the newborn, and methods of immunisation could be devised which would be most satisfactory for most of the babies.

EXPERIMENTAL

In the work here described we have tested the antitoxic level in the cord blood of each baby, and investigated the level of antitoxin which will interfere with active immunisation by two doses, each of 0·5 ml. of A.P.T. (50 Lf per ml.). The influence of age on response has also been considered. In some cases the amount of antitoxin remaining in the baby's blood at the time of the first injection was obtained by calculation from the antitoxic level in the cord blood, and in others it was obtained by titrations of a blood sample. The techniques adopted for taking blood samples and estimating antitoxic levels were those already described by us.[3]

EFFECT OF AMOUNT OF PASSIVELY ACQUIRED ANTITOXIN ON RESPONSE TO IMMUNISATION

Table I shows the antitoxic levels of babies about two months after the second injection of 0·5 ml. of A.P.T. The results have been grouped according to the amount of passive antitoxin present at the time of the first injection, and one group has been further subdivided according to age. An amount of passive antitoxin less than 0·02 unit per ml. does not interfere with active immunisation under the conditions here present. The 10 babies with titres of 0·01–0·02 unit per ml. responded as well to immunisation as did 31 babies of similar ages but with less passive antitoxin; the geometric means of the titres reached were 0·272 and 0·250 respectively. The logs of the levels attained by all the babies with less than 0·02 unit of passive antitoxin per ml. at the time of the first injection showed a good approximation to a normal distribution ($\chi^2 = 3{\cdot}019$ — $P = 0{\cdot}397$); and the mean value of 0·265 unit per ml. for the group, about two months after the second injection, is satisfactory. The values recorded in the tables include values up to the next figure given—e.g., 0·2 unit includes values between 0·2 and 0·5 unit. Hence in calculating the geometric means of groups each value has been taken as the geometric means of the limits within which it lay, tests having been made at about 100% differences. Group D, composed of babies with 0·02–0·04 unit of passive antitoxin per ml., is small, but the geometric mean of the values is definitely lower than those of groups A, B, and C, and this is also the case with group E,

TABLE I—ANTITOXIC RESPONSE OF BABIES TO TWO INJECTIONS, EACH OF 0·5 ML. OF A.P.T.: BABIES GROUPED ACCORDING TO THE TITRE OF PASSIVE ANTITOXIN PRESENT AT THE TIME OF THE FIRST INJECTION

Group	Passive antitoxin at time of 1st injection (unit/ml.)	Age (weeks)	No. of babies producing titres (unit/ml.)								Total no.	Geometric mean (unit/ml.)	Av. interval (weeks) between

F	0·10–0·20	Av. 18·2	3	1	..	1	..	..	..	..	5	<0·020	8·2	8·2

which had 0·04–0·1 unit per ml. at the time of injection. One baby produced 1 unit per ml., but the values, taken as a whole, were lower, and it seems that in group E the passive antitoxin interfered with the first dose of prophylactic in about half the babies. It is possible that the response in these groups was delayed and a slow rise may still have been in progress when the samples of blood were taken. The responses of babies in group F show that the large amount of passive antitoxin present interfered considerably with the start of immunisation.

EFFECT OF AGE

Consideration of groups A, B, and C suggests that a better response is obtained with babies in the younger age-groups. Though the numbers are small, this suggestion is supported by the progressive slight decrease in the mean antitoxic values from A to C and by the greater number of low values (0·02 and 0·05 unit per ml.) in group C. The differences might be accounted for by differences in weight, because the same doses were injected into all the babies and the average weights of group C would be nearly double those of group A. This would lower the effective size of the primary stimulus in two ways: (1) the dose/weight ratio would be lower in the heavier babies; and (2) though the titre of passively conferred antitoxin in units per ml. was the same for all groups, the total amount of this passive antitoxin present in the circulation would be greater in the older and bigger babies. It is thus very probable that the passive antitoxin would interfere with immunisation more in the heavier children. If this is so, the question of large initial doses is of very great importance if immunisation is not done in the first few months of life. There is a further possibility that some degree of poor immunisability might be acquired after the first few months of life.

In group A 5 babies received their first injection at the age of 6–8 weeks, and the geometric mean of their antitoxic values after immunisation was 0·314 unit per ml., compared with 0·329 unit per ml. for the whole group. These results show that successful immunisation is possible at a very early age.

EFFECT OF INTERVAL BETWEEN INJECTIONS

Table II shows the antitoxic values of babies injected with two doses of A.P.T., each of 0·5 ml., given at different intervals. The numbers in each group are small, but in babies immunised before the age of 6 months (groups A and B) there is strong evidence that better responses were obtained as the interval between injections was increased. In group C, composed of babies over the age of 6 months, this improvement did not occur. The difference between the age-groups, if significant, may again be due to the reduced effect of the primary stimulus, owing to the greater weight and greater total amount of circulating antitoxin in group C. Though, in general, higher values are obtained by increasing the interval between primary and secondary stimulus, this is not the case if the primary stimulus is small.[4]

TABLE II—INFLUENCE ON RESPONSE OF INTERVAL INJECTIONS OF A.P.T. IN BABIES WHOSE PASSIVE A LEVELS WERE BELOW 0·02 UNIT PER ML.

Group (see table I)	Weeks between injections	No. of babies producing titres (unit/ml.)						Total no.

COMPARISON OF RESPONSES OF EXPECTANT MOTHERS BABIES TO IMMUNISATION

Some expectant mothers at Guy's Hospital Schick tested in the fourth month of pregnancy, an positive reactors were immunised with two doses and 0·5 ml., of A.P.T. By this means we ensured some babies would be born with large amounts of maternally transmitted antitoxin, the rate of which could be followed for a considerable time part of the experiment has been described previous

The scatter of antitoxic values after immunis babies in groups A, B, and C in table I is relatively 59 out of 61 titres were over 0·04 unit and unde units per ml. The remaining two levels were bet *0·02 and 0·04 unit and* were produced by babies the oldest age-group. Table III shows how immunised expectant mothers produced titres above, between, or below these limits (over 0·04 and under 2·0 units per ml.). The women were d into those who had been Schick tested and found (group L), those not so tested but found to have less *0·001 unit of antitoxin per ml.* in their serum immunisation (group N), and those with antitoxic levels which ranged from 0·01 to 2·0 per ml. (group P). In addition to these women were two with high antitoxin levels at the time of first injection of A.P.T.; one had 2–5 units and the 10–25 units per ml.; neither showed any ap rise after immunisation, the recorded values being units in the first woman and 12–15 units per ml. in second. Since all the other expectant mothers in produced 6 or more units per ml., it seems that a of 2 or more units per ml. may interfere with respon actively immune persons to the injection of 0·2 ml A.P.T., compared with interferences by 0·1 or more per ml. in passively immunised babies injected 0·5 ml. of A.P.T.

Women with little or no circulating antitoxin, Schick-positive (L) or with titres below 0·001 unit ml. (N), appear to fall into three groups: (1)

TABLE III—ANTITOXIC VALUES REACHED BY EXPECTANT MOTHERS AND BY BABIES AFTER IMMUNISATION WITH A. THE MOTHERS HAVING RECEIVED TWO DOSES OF 0·2 AND 0·5 ML. AND THE BABIES TWO DOSES EACH OF 0·5

---

4. Barr, M., Glenny, A. T. *J. Hyg., Camb.* 1945, 44, 135.

give similar results to babies who almost certainly not actively immune before injection; (2) those do not respond; and (3) those whose production of oxin is considerable and who can be accepted as g into the category of "potentially immune without lating antitoxin." The antitoxic values reached by potentially immune women in groups L and N est that preliminary Schick testing may have some ence on immunisation, though the numbers involved very small; 3 out of 4 not Schick tested gave lower ues (2, 3, and 5 units per ml.) than those tested, only out of 6 of whom gave titres below 10 (6 and 8) units ml. Of the others, the remaining untested mother roduced 13·5 units per ml., and the 4 other tested others produced 15, 30, 30, and 100 units per ml.

Thus, of 26 adults below the Schick level of immunity, were very poor responders to immunisation, about 9 ave normal responses, and about 9 were potentially mune. It is impossible to decide definitely whether ose women producing 2–5 units per ml. were potentially nmune or not, though no baby we have yet tested has roduced 2 units or more per ml.

It appears probable that all in group P and those in L and N who were potentially immune would have sponded strongly to a single injection of prophylactic; f 23 Schick-positive women whose immunisation was iscontinued after the first injection of 0·2 ml., one was bviously potentially immune and produced 15 units er ml.

ABLE IV—RESPONSES OF EXPECTANT MOTHERS AND THEIR BABIES TO IMMUNISATION WITH A.P.T.

ase no.	Response of mother (cord-blood value) (units/ml.)	Antitoxin value of baby when injected (unit/ml.)	Age (weeks)	Interval between		Response of baby (unit/ml.)
				1st and 2nd injections	2nd injection and blood sample	
1	0·002	< 0·001*	19	16	9	1·0
2	0·002	< 0·001*	10	12	20	0·2
3	0·004	< 0·001	31	9	7	0·2
4	0·01	< 0·001*	10	11	9	0·1
5	0·2	< 0·001	36	12	8	0·04
6	0·5	0·004	27	10	10	0·1
7	1·0	0·002	32	9	7	0·2
8	1·0	0·01*	22	11	9	0·2
9	25	0·01*	37	8	8	0·02
10	25	0·02*	37	11	13	0·04
11	120	0·01	61	8	8	0·2

Values obtained by titration of blood sample; the remainder were calculated from the cord-blood value.

Table IV compares the antitoxic responses of 12 mothers and their babies; there seems to be no correlation between the response of the mother and that of her baby.

DISCUSSION

Only one factor has been kept constant in all these experiments on immunisation of babies—i.e., all received two doses of A.P.T., each of 0·5 ml. Any conclusions drawn from the results, regarding optimum interval between injections, or the level of maternally conferred passive antitoxin causing interference with active immunisation, can only be applied to the active immunisation of babies with two doses of 0·5 ml. of A.P.T. This must always be borne in mind because, if the first dose of A.P.T. were 0·3 ml., a lower level of passive antitoxin would bring about interference so that immunisation would have to be delayed for a slightly longer time after birth, and the optimum interval between injections would be shorter.[4] The effect of giving this lower dose is entirely disadvantageous from the immunological standpoint, because the larger the initial dose the longer is the interval which can with advantage be allowed before the second dose, and both these factors bring about the establishment of sound basal immunity. Nor does there seem to be any good reason for injecting young babies with small doses, since reactions are not encountered among them and they do not show any adverse emotional disturbances.

TABLE V—PERCENTAGE OF BABIES WHOSE PASSIVE MATERNALLY ACQUIRED ANTITOXIN WOULD BE BELOW 0·04 UNIT PER ML. AND BELOW 0·004 UNIT PER ML. AT VARIOUS AGES. BOTH SETS OF FIGURES WERE CALCULATED FROM ANTITOXIC VALUES OF 200 RANDOM CORD-BLOOD SAMPLES FROM SOUTH-EAST LONDON

Age (weeks)	Percentage of babies with passive antitoxin	
	Under 0·04 unit/ml.	Under 0·004 unit/ml.
0	36·5	26·0
4	56·4	31·8
13 (3 months)	83·7	38·3
17	91·0	50·0
21	95·2	60·6
26 (6 months)	98·7	76·4
28	100·0	83·1
39 (9 months)	. .	96·9
43	. .	100·0

Our results (table I) show that 61 babies whose level of passive antitoxin had fallen below 0·02 unit per ml. were all satisfactorily immunised, the chief variables being age (from 6 weeks to over 6 months) and interval between injections (6–18 weeks). The facts that there were no failures in this group, and that the antitoxic values after immunisation were normally distributed and showed small scatter, provide strong evidence that these babies were adequately immunised, so long as their antitoxin and their basal immunity are retained until they receive a boosting dose. This conclusion may also apply to the small group D (table I) in which the level of passive maternal antitoxin had fallen to 0·02–0·04 unit per ml. at the time of the first injection of A.P.T., but in group E, with 0·04–0·1 unit per ml. when injected, there were indications of unsatisfactory responses, though 1 baby out of 6 produced 1 unit per ml. It should be noted here that all in this small group, and at least 2 out of 5 in group F, would presumably have been Schick-negative at the time of the test on the blood samples, and it therefore appears to us that in all fundamental work designed to throw light on methods of immunisation the Schick test should be avoided, except to detect on a much larger scale the numbers of very bad responders to any particular treatment, and to confirm the need or otherwise of boosting doses at a later age. Schick testing does not reveal the scatter of antitoxic values, which, after satisfactory immunisation and in the absence of previous *natural or artificial stimulation, should be small.* Very little attention has been paid in the past to the scatter of antitoxic values, or to the type of their distribution. We are convinced that a small scatter of values normally distributed is a sure proof that the course of immunisation has been satisfactory, and it appears that the Schick test is insufficiently stringent to apply to recently immunised populations, because many people who have produced only traces of antitoxin (over 0·002 unit per ml.) are Schick-negative and on the results of the test would therefore seem to be satisfactorily immunised.

The questions of size of first dose, interval between injections, and duration of resulting antitoxin are all linked together. We have evidence from animal experiments that actively produced antitoxin is retained for a longer time when the interval between two injections of prophylactics can be extended beyond four weeks; the optimal interval to ensure a good antitoxic response depends in turn on the size of the first dose. Thus the duration of antitoxic immunity, in the form of circulating antitoxin, depends on the size of the first dose, which, if large, also establishes good basal immunity or power to respond to further stimulation in the form of further injections of prophylactic or chance infection. As immunisation of the population becomes more general, encounters with chance infections would be expected to become less numerous; therefore a sound course of artificial immunisation should be aimed at, if antitoxic values are to be maintained.

Our results suggest that an initial dose of 0·5 ml. of A.P.T. is sufficient in babies whose levels of maternally acquired passive antitoxin are below 0·02 unit per ml., but there is a suggestion that this might not be so in older infants and adults, because in babies over 6 months old the response to immunisation was not improved by increasing the interval between injections beyond nine weeks, as in the younger babies. This, as mentioned earlier, might be explained by the fact that the total amount of passive antitoxin would be greater in the older and heavier babies, but the possibility of inadequate dose in relation to weight cannot be excluded. The levels reached by expectant mothers with little or no antitoxin (table III) strongly suggest that two doses, 0·2 and 0·5 ml., of A.P.T. were inadequate. Assuming that 9 mothers out of 26 in table III were already potentially immune and 17 non-immune at the time of the first injection, 8 of the 17 did not respond adequately to immunisation. There is a need for further work on the immunisation of adults. It is possible that a much larger dosage is needed and that this can only be achieved by giving purified toxoid or some derivative therefrom after testing for sensitivity, or by giving a longer course of immunisation with a mild prophylactic. The average weight of the expectant mothers can be taken as at least eight times that which their babies will attain at the age of 3 months and at least six times that of their babies at 6 months.

The high proportion of potentially immune women with little or no antitoxin at the time of the first injection of prophylactic may account for the occasional occurrence of clinical diphtheria in the presence of a considerable amount of antitoxin. The time interval between the production of small amounts of toxin by the invading organism and the first indications of illness may be less than the latent period before the production of antitoxin. If to this interval be added the time elapsing between the onset of illness and admission to hospital, sufficient time may have elapsed for antitoxin to be produced.

In our previous paper[3] we gave figures for the antitoxic values of 100 random samples of cord blood from each of two South-East London districts and showed that the difference in distribution of the values for the two sets was not significant ($\chi^2 = 5{\cdot}719 - n = 6$; $P = 0{\cdot}46$). By the formula for rate of loss of maternally transmitted antitoxin, to which we have already referred, it is possible to calculate the average number of babies from these areas whose passive antitoxin has decreased at any given time to some chosen level. In table V we record the percentage of babies whose passive antitoxic level would have fallen below 0·04 unit per ml., and in whom active immunisation could be started, and the percentage whose levels would be below 0 004 unit per ml. and would thus be expected to be Schick-positive. Work now in progress suggests that these figures for South-East London are not of general application elsewhere. The figures show that over 80% of the babies in this population could benefit by a first dose of 0·5 ml. of prophylactic at the age of 3 months, though only 38% would be expected to be Schick-positive. At 4 months immunisation of 91% could be started (50% Schick-positive), but just over 6 months would have to elapse before the levels of passive antitoxin of all babies fell below 0·04 unit per ml. At this age, however, 83·1% would be below the Schick level, and many would have been totally unprotected for several weeks.

It seems probable that all babies, except th of potentially immune mothers who received immunisation during pregnancy, could be su immunised by three injections of prophylactic the ages of 3, 6, and 18 months. Those in the mentioned population whose passive antitoxin with the first dose of prophylactic would respond second injection, in some cases by giving an response and in the remainder by the est basal immunity. All the babies should then give antitoxic response to a third injection given at of 18 months. Better results could be expected wit dose of 1 ml. of prophylactic or with 0·5 ml. of a s prophylactic.

SUMMARY

Babies were actively immunised with two inj of A.P.T., each of 0·5 ml., given at an interval weeks or more. Conclusions reached as a result work can therefore be applied only to schemes in this particular dosage is given, and not to th which the first dose is 0·2 or 0·3 ml. The adva of giving as large a first dose as possible are dis since there seems to be no sound reason for using doses in young babies.

When the level of maternally conferred an in the baby had fallen below 0·04 unit per ml. time of the first injection, there was no interferenc active immunisation; but when this level was 0·1 unit per ml. immunisation was unsatisfactory.

A group of 61 babies with levels below 0·02 unit when injected produced normally distributed lo toxin levels with a small scatter; this is taken as ev of satisfactory immunisation.

Twenty babies were successfully immunised wh first injection was given between the ages of 6 weeks; 5 of the babies were under 2 months old. was a slight suggestion of poorer response in babies immunisation was started after the age of 6 mon

Higher antitoxic values were obtained in immunised before the age of 6 months when the injection of A.P.T. was given 10–18 weeks rathe 6–9 weeks after the first. This was not so in over 6 months old. Reasons for this are suggested

By calculation from antitoxic values of cord it is estimated that over 80% of a population babies born in South-East London could be succes immunised, starting at the age of 3 months. It i gested that all babies, except those born of poten immune mothers further immunised during pregn could be successfully immunised with three [illegible] of prophylactic given at the ages of 3, 6, and [illegible] Figures are also given of the estimated Schick-p rate of babies from this area at different ages.

Active immunisation of expectant mothers sh that of those with little or no antitoxin at the time first injection about a third responded badly, a were potentially immune and produced high titr antitoxin, and a third responded in a similar mann the babies.

There was no correlation between the respon immunisation of expectant mothers and of their ba

The Schick test should not be used in fundam work designed to throw light on methods of immu tion. It is insufficiently stringent and does not r the scatter of values, which should be small. Its of usefulness is essentially confined to routine wor

We wish to thank the staffs of the obstetric departme Guy's Hospital and St. Alfege's Hospital for their [illegible] particularly Miss L. Coombe, superintendent [illegible] at Salomon's Welfare Centre; and Miss F. Anderson, B. Cripps, Miss D. Delahoy, and Mr. A. Service for tech assistance in the antitoxin estimations.

ITUITARY ADRENOCORTICOTROPIC IORMONE (A.C.T.H.) AS A TOOL OF INICAL AND LABORATORY RESEARCH

TOM D. SPIES

ROBERT E. STONE *
M.D. Harvard
CIATE DIRECTOR, NUTRITION CLINIC, HILLMAN HOSPITAL

.C.T.H. seems to be the most promising tool medical stigators have today. It is our working hypothesis it acts through a fundamental biochemical system he body, with the result that the metabolism of all cells is affected. The fact that patients with such erent syndromes as are reported here and elsewhere ond to A.C.T.H. supports the concept of its wide ge as a tool of research. That at present it must be sidered only for use in research is obvious because its great scarcity and the side-effects which may, often do, develop.

hen A.C.T.H. is injected into a person with normally ctioning suprarenals, the sterol 17-hydroxy-11-ydrocorticosterone and other substances are promptly med. These materials have a profound effect in man, before discussing our experiences with them perhaps s best to say a few words about sterols in general. g ago chemists found in certain animal and vegetable fats an unsaponifiable material. This material was insoluble in water and could not be made into a soap by boiling with an alkali. Eventually these compounds were called steroids, and it was learnt that they are far more complex in structure than the fats. They contain rbon, oxygen, and hydrogen and are soluble in most the organic solvents. The sterols contain what is rmed the cyclo-penteno-phenanthrene ring, which can regarded as a condensed carbon-ring structure (fig. 1). fig. 2 shows, 17-hydroxy-11-dehydrocorticosterone Cortisone') contains this grouping.

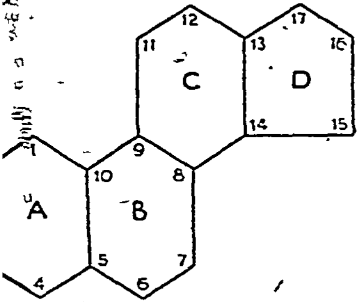

Fig. 1—Cyclo-penteno-phenanthrene.

The prompt amelioration of the symptoms of rheumaid arthritis after the injection of synthetic cortisone A.C.T.H. was first reported by Hench et al. (1949). heir findings with cortisone have been confirmed by oland and Headley (1949); and Spies and Stone 949a), Spies et al. (1949), and Markson (1949) have ported the relief of gouty arthritis after the administration of A.C.T.H. Hench et al. have also noted that soriasis associated with arthritis is relieved. Thorn t al. (1948) have shown that the number of circulating sinophils in persons with intact suprarenals decreased apidly after the injection of A.C.T.H., and we have used his as a screening method to study A.C.T.H. (Spies and Stone 1949b). So far as we know, no-one has reported he amelioration of symptoms of allergic states with this material.

The present report describes the response of a patient with acute rheumatoid arthritis to A.C.T.H. and his failure to respond so well, if at all, to some chemical compounds (sterols) closely related to cortisone. It also describes the response to A.C.T.H. of a patient with rheumatoid arthritis, chronic eosinophilia, and asthma: of a patient with gout; and of a patient with psoriasis and rheumatoid arthritis. Some of the side-effects are discussed.

234

CASE 1

A white married man, aged 64, had worked actively as a bridge-construction carpenter until forced to retire because of his present illness. In April, 1947, he first had pain and stiffness, chiefly in the right hand, knee, and shoulder. The symptoms were mild and of very short duration. Since then he has had frequently recurring pain and severe stiffness and tenderness which gradually involved more and more joints, particularly the hands, wrists, elbows, shoulders, feet, and knees. The symptoms tended to persist longer with each attack, and, though the severity subsided somewhat, some stiffness and disability remained. Eventually the patient was forced to discontinue working, because of intense pain. He noticed that the symptoms were worse during cool damp weather and more pronounced early in the morning than in the afternoon. During the past year he has had recurrent soreness and burning of the mouth and tongue, associated with gastro-intestinal distress and mild diarrhœa. He consulted several physicians, who prescribed various remedies with little or no relief.

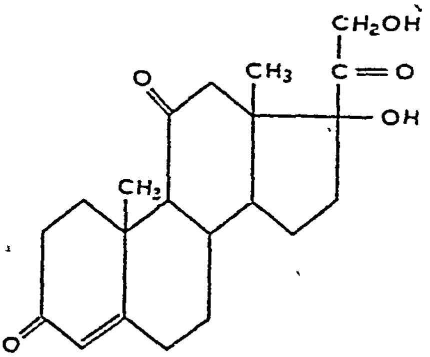

Fig. 2 — 17-Hydroxy-11-dehydrocorticosterone ('Compound E' of Kendall, 'Compound F' of Wintersteiner and Pfiffner, and 'Substance Fa' of Reichstein).

Physical examination showed a large heavily built man who appeared to be in moderate distress. Walking was difficult and laboured; his gait was slow, deliberate, and stiff. He had considerable difficulty in rising from a sitting position, in removing his coat, and in elevating his arms. Every time he moved he had great pain. The conjunctivæ and finger-tips were slightly pale. The tongue was large and moderately red. He was edentulous. The gums were essentially normal. There was moderate swelling, with tenderness and limitation of motion in all the joints of the hands, wrists, feet, and ankles, and some limitation of the shoulders and knees. The joints were tender to touch but not red. The patient was comfortable at rest but in distress in motion, particularly in walking.

Laboratory Findings.—Analysis of the urine was negative. Gastric analysis showed no free hydrochloric acid in the gastric juice after histamine stimulation. Blood: seven uric-acid determinations ranged from 4·35 to 4·80 mg. per 100 ml.; non-protein nitrogen (N.P.N.) 31·5 mg. per 100 ml.; sugar 122 mg. per 100 ml. fasting; total cholesterol 179 mg., esters 110 mg., and free cholesterol 59 mg. per 100 ml. Red blood-cells 2,200,000 per c.mm.; Hb 7·1 g. per 100 ml. (46%): reticulocytes 1·6%. Packed cell volume (P.C.V.) 24 ml. per 100 ml.; mean corpuscular volume (M.C.V.) 109 c.μ; mean corpuscular Hb (M.C.H.) 32 $\mu\mu$g.; mean corpuscular Hb concentration (M.C.H.C.) 29·5%. Differential leucocyte-count: polymorphs 52%, eosinophils 3%, basophils 2%, lymphocytes 36%, monocytes 7%. The erythrocyte-sedimentation rate (E.S.R.) varied from 60 to 69 mm. in 1 hr. (corrected 16–22 mm./hr.).

Treatment and Progress.—The patient was given 15 mg. of A.C.T.H. (Armour Standard) every four hours until sixteen intramuscular doses had been given. Within twenty-four hours after the initial injection of A.C.T.H. there were considerable relief of pain, decreased swelling of the joints, less limitation of movement, and less difficulty in rising from a sitting position and in walking. The patient could close his hands with ease and walk up and down stairs without difficulty—a thing he had been unable to do for many months. There was progressive lessening of pain with improvement in joint function until he had no symptoms in motion. Soon after the beginning of treatment he had a remarkable boost in sense of well-being, increasing to the point of elation.

---

* Clayton Foundation Fellow.

During several weeks of observation before the injection of A.C.T.H. the blood-pressure had ranged from 98/48 to 104/58 mm. Hg. During the four days of treatment it ranged from 108/52 to 130/66. Before the injections were started, the patient's greatest weight was 186 lb. After the fourth injection of A.C.T.H. he developed slight œdema of the ankles and feet. Three days later his body-weight was $197^{1}/_{2}$ lb. and he had bilateral pitting œdema of the ankles. By the second day after the injections were discontinued his body-weight had decreased 2 lb., and a week later it was 184 lb. There was considerable diuresis associated with the loss of weight, and the pitting œdema disappeared. There was little change in the red-cell count or in the Hb content; the E.S.R. decreased slightly; and the blood-pressure returned to its initial level.

About twelve days after the last injection the symptoms began to return. Within eight weeks the patient had disability of all the joints of the hands and wrists and limitation of movement, pain, swelling, and tenderness of the feet, ankles, and knees, which was more severe in the early morning. These symptoms were almost as severe as they had been before A.C.T.H. therapy; the patient again could not dress himself or get up or down without assistance, and he could walk only with extreme difficulty.

Effect of Other Sterols.—Eight weeks after A.C.T.H. therapy was discontinued, the patient had definitely relapsed. Since our supply of A.C.T.H. was exhausted and the patient wished to be treated, we decided to administer the following compounds in the order in which they are listed:

Pregnene-(4)-triol-(17α, 20β, 21)-one-(3)-diacetate
Pregnane-3, 12, 20-trione
17-MethylΔ5-androstendiol-3 (β), 17 (α)
17-α-Hydroxyprogesterone
17-α-Hydroxy-11-desoxycorticosterone-21-acetate
Deoxycortone (desoxycorticosterone) acetate
Ergostanyl acetate

These compounds were administered over four days. In each twenty-four hours a total of 200 or 300 mg. was given in divided doses, except for deoxycortone acetate, of which a total of 20 mg. was given. Many of these sterols were difficult to get in suspension. Some of them were suspended in saline and injected intramuscularly. Others were suspended in a mixture of benzyl alcohol and various oily solvents. In no instance was there any improvement comparable to the effect of A.C.T.H. There was slight amelioration in some of the symptoms after the administration of ergostanyl acetate, but this could well have been a slight spontaneous remission. No objective changes were apparent.

Second Course of A.C.T.H.—During the six weeks that these compounds were under test the symptoms progressed until the patient could not turn over in bed or walk without assistance; so we decided to administer A.C.T.H. again. It was given in five injections, six hours apart, 10 mg. in each injection. Again there was prompt improvement. Within twelve hours from the time of the first injection there was beginning relief of the soreness and stiffness of the joints. Within twenty hours the patient could get out of a chair without assistance, walk with ease, go up and down stairs without difficulty, and shave; he again became interested in eating; and he felt better in general. Since no more A.C.T.H. was available, it was discontinued; and within a week the symptoms were almost as severe as before treatment.

Case 1 is representative of 5 cases of rheumatoid arthritis which had been under observation for a year or more. The duration of the disease varied from one to four and a half years. Each of the other 4 patients had moderately severe articular swellings and pain on motion, some elevation of E.S.R., and the constitutional symptoms of pronounced loss of appetite, weakness, and general lassitude. The symptoms in each case were relieved by A.C.T.H., but they were not relieved by any of the other seven sterols except ergostanyl acetate, which produced slight amelioration of symptoms in case 1. This study demonstrates the great specificity of A.C.T.H.

CASE 2

A white man, aged 61, came to the Nutrition Clini
plaining of pain in the right shoulder, elbow, hand, an
and in both knees. Twelve months previously he
having pain in his right shoulder. Within two mon
was unable to raise his right arm above shoulder
Gradually the pain involved the right elbow, hand, an
and both knees. The pain increased in cold, damp w
and was worse at night than in the morning.

Physical examination showed a well-developed and
what overweight man who appeared to be in pain wh
moved. The joints of both knees and of the right
elbow, and shoulder were tender. The right hand w
swollen that the patient could not close it. He had diff
in rising from a sitting position and could not raise his
arm above shoulder level.

Laboratory Findings.—Blood-uric acid was 6·7 mg
100 ml. or more on repeated determinations. N.P.N. 38
per 100 ml. Fasting blood-sugar 122 mg. per 100 ml.
cholesterol 125 mg., esters 86 mg., and free cholesterol 3
per 100 ml. Total serum-proteins 7·15 mg., serum-alb
4·46 mg., and serum-globulin 2·69 mg. per 100 ml.
cells 5,310,000 per c.mm.; white cells 6000 per c.
Hb 13·6 g. per 100 ml. (88%); reticulocytes 0·5%;
44 ml. per 100 ml.; M.C.V. 83 c.μ; M.C.H. 25·5 μμg.; M.
31%. Differential leucocyte-count: polymorphs
eosinophils 1%, lymphocytes 23%, monocytes 8%.
E.S.R. varied between 16 and 20 mm. in 1 hr.

Treatment and Progress.—Mild atypical gout was diag
and the patient was given a single 30 mg. dose of A.
intramuscularly. About 30 min. after the injection
was less pain in the right shoulder, elbow, hand,
and in both knees, and less swelling of the right hand.
patient could raise his right hand above his head fo
first time in three months. Twelve hours after the inj
the swelling of the right hand and all the soreness i
joints had disappeared. At the present time, four m
after A.C.T.H. therapy, there has been no recurrence of
in any of the joints. The patient is working steadily.

There was essentially no change in the laboratory fin
except as regards uric acid. Two days after therapy
uric acid was 4·20 mg. per 100 ml.; four days later it
1·7 mg. per 100 ml.; and two months later it was 3·
per 100 ml.

Three other patients, all with severe gout,
received relief from symptoms of acute attack whe
A.C.T.H. injections were started early enough.

CASE 3

A white married woman, aged 31, came to the Nutr
Clinic complaining of "psoriasis" and "rheumatism."
psoriatic lesions first appeared on the scalp when she
9 years old. Seven years later they appeared on her c
and abdomen. They varied in severity according to
time of year, being worse in the winter than in the sum
Some proprietary remedies applied locally occasion

On several occasions the symptoms almost disappeared
various lengths of time, the longest being during her
pregnancy, when she was aged 21. During her se
pregnancy, a year later, they did not subside. Through
years she noticed that with each exacerbation they
worse. The swelling of the thumb of the left hand b
during her first pregnancy. Gradually the joints of
hands and feet became involved. Though there had
periods of partial remission, the symptoms never subs
entirely. The progression had been slow to the poin
moderate disability in the use of the hands and feet.
patient tried numerous "home remedies," as well as d
prescribed by physicians, without any definite beneficial e
on the joint pain, swelling, and stiffness.

Physical Examination.—There were several large circ
lesions on the abdomen, measuring up to 3–6 in. in diam
with typical psoriatic elevation, redness, and scaling. A s
lar lesion was present over the sacrum, smaller lesions v
scattered over the lower back, upper cervical area, and sc
[illegible] joints of the hands were seve
[illegible] largement and limitation of mot
Several joints were slightly discoloured and modera
tender. The fingers of the left hand were fixed in a parti
flexed position. There was moderate limitation of mo
of the wrists. The feet were similarly, but considerably

olved. Disability of the hands was apparent. Disability the feet was noted only in walking; they appeared stiff en the patient started to move. The finger and toe nails re definitely ridged and rough and in areas appeared be partially separated from the nail beds.

Laboratory Findings.—Blood-uric acid was 3·8 mg. per 100 . N.P.N. 32·5 mg. per 100 ml. Fasting blood-sugar 85·1 mg. 100 ml. Total serum-proteins 6·64 mg., serum-albumin 4 mg., and serum-globulin 2 mg. per 100 ml. Red cells 40,000 per c.mm.; white cells 7700 per c.mm.; Hb 13·4 g. r 100 ml. (86%); reticulocytes 1%. Differential leucocyte-unt: polymorphs 63%, eosinophils 2%, basophils 2%, nphocytes 27%, monocytes 6%. E.S.R. 21 mm. in 40 min.

Treatment and Progress.—The patient was given 15 mg. A.C.T.H. six-hourly until eighteen doses had been given. ithin seventy hours after the beginning of treatment me amelioration in the skin lesions was noted; the intensity the colour had faded somewhat, the lesions seemed to subsiding centrally, and itching, fever, and scale formation ere somewhat less. Within the next twenty-four hours ere was slight improvement in the joint signs and symptoms arthritis, particularly in the swelling and tenderness of e finger joints, and there was less discoloration of these ints. During the next few days the patient could use her nds better than she had been able to for years and she had ss discomfort of the feet. Throughout the treatment the in lesions continued to subside but not to the point of mplete clearing. The patient experienced a remarkable ychological elation or stimulation from treatment; she id over and over again that A.C.T.H. was the only therapy hich had ever relieved both the psoriasis and arthritis. er body-weight on admission had been 123 lb. Six days ter it was 130 lb. During the first four days after the .C.T.H. injections had been discontinued the body-weight ecreased from 130 to 122 lb. This was associated with iuresis. The blood-pressure during the period of injections A.C.T.H. varied from 108/70 to 122/76 mm. Hg. The ulse-rate varied from 84 to 124 per min. There was no ange in the E.S.R.

A week after therapy was discontinued there was evidence at the skin lesions were becoming worse. They became deeper violaceous hue and thicker. At this time the atient experienced a moderate emotional upset as regards he skin lesions which had flared up. Until this time there as no evidence that the joint lesions had resumed activity, ut within about two weeks after treatment the signs and ymptoms of arthritis began to recur.

CASE 4

A white housewife, aged 59, came to the Nutrition Clinic omplaining of periodic attacks of asthma, hay-fever, urticaria, and pain and aching in the wrists, hands, knees, and ankles. Her father and her son have asthma and "hives." For at least twenty-five years the patient has been having mild periodic attacks of asthma characterised by difficulty in breathing, associated with a "breaking out" on the arms, hands, and face. She had observed that these attacks were also associated with an "upset stomach" and headache. Nine years previously she begun having pain and aching of the joints, especially the wrists and knees.

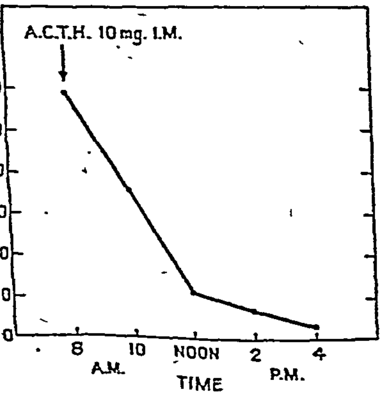

Fig. 3—Eosinophil-count in case 4 under treatment with A.C.T.H.

Physical examination showed a well-developed woman. On the arms, hands, neck, and face there was evidence of residual eczematous dermatitis. There was no difficulty in breathing at the time of examination. The patient sneezed often and had almost constant "watering" of the nose and eyes. The right wrist and the index finger of the right hand were swollen, and she could not close this hand. The knees were swollen and felt hot to touch. The ankles were tender and swollen.

Laboratory studies repeatedly showed an absolute eosinophil-count ranging between 1000 and 3000 per c. mm. The patient had thick tenacious sputum containing many eosinophils.

Treatment and Progress.—The patient was given 10 mg. of A.C.T.H. intramuscularly twice daily for four days. On the day following the initial dose the soreness of the right hand and wrist and of the knees and ankles disappeared, and the swelling of the wrist, knees, and ankles began to subside. The sneezing and the "watering" of the nose and eyes ceased at this time. By the following day the patient was free from pain, and the swelling of the right wrist, knees, and ankles disappeared. Her appetite, which was poor before therapy, became excessive. She volunteered that she "felt cheerful" and better than she had for many years. There was no return of symptoms for ten days after therapy had been discontinued, but at the end of this time she began to have slight soreness of the right wrist. Occasional pain in the knees and ankles and slight swelling of the wrist began a week later. These symptoms have persisted but they have not increased in severity during the three months that have elapsed since A.C.T.H. therapy was discontinued, and there has been no recurrence of asthma or urticaria.

The eosinophil-count decreased toward normal (fig. 3) and remained low until A.C.T.H. therapy was discontinued. Within three days after the A.C.T.H. injections had been discontinued the eosinophils returned to their previous high level. The number of eosinophils in the sputum greatly decreased within a few hours after the first injection.

SUMMARY AND CONCLUSIONS

Repeated intramuscular injections of 25 mg. of pituitary A.C.T.H. were well tolerated during a short period of administration. There was prompt relief of symptoms in 5 patients with rheumatoid arthritis, 3 with gout, 1 with rheumatoid arthritis and psoriasis, and 1 with rheumatoid arthritis, asthma, hay-fever, urticaria, and chronic eosinophilia of unknown origin.

Amelioration of the symptoms and disappearance of swelling and tenderness of the joints in the patients with rheumatoid arthritis and those with gout began on the first or second day of therapy. There was a sharp decrease in the circulating eosinophils within four hours. The patients with rheumatoid arthritis relapsed within 3–14 days of the end of treatment. Within 96 hours after the last injection the patients had a diuresis with a loss of body-weight and a decrease of blood-pressure to the initial levels. Seven sterols resembling cortisone in structure were administered one at a time, but with little or no decrease in symptoms. Each patient was then given injections of A.C.T.H. again, and prompt and dramatic improvement followed. The side-effects are of considerable interest; we observed water retention with an associated gain in body-weight, some increase in blood-pressure, and pronounced "elation" in some patients.

These studies throw no light on the mechanism by which A.C.T.H. relieves the symptoms arising from rheumatoid arthritis, gout, asthma, hay-fever, urticaria, and psoriasis, or why the circulating eosinophils decrease in number after its administration. They are clinical leads for vigorous experimental studies. One needs to know the effect on the pituitary and the suprarenal glands. Perhaps if this were known we would know how to maintain normal function of these glands. If the protective substances made by these glands could be augmented by giving proper nutrients it might prove desirable. It is significant that persons with Addison's disease or Simmonds's disease do not have rheumatoid arthritis, gout, or psoriasis as an integral part of their syndromes. Do such persons have some way of utilising the proper raw materials to prevent the development of these diseases?

This study was aided by grants from the Martha Leland Sherwin Memorial Fund and the Birmingham Citizens Committee Fund. The pituitary adrenocorticotropic hormone

was obtained through the courtesy of Dr. Kenneth W. Thompson, of Organon Inc., and Dr. John Mote, of Armour Laboratories.

COMPARATIVE SERUM TESTING WITH CARDIOLIPIN AND STANDARD WASSERMANN ANTIGENS

REVIEW OF 5124 TESTS

I. N. Orpwood Price

PATHOLOGIST, WHITECHAPEL CLINIC; DIRECTOR

A. E. Wilkinson
M.R.C.S.
ASSISTANT PATHOLOGIST TO THE CLINIC; SEROLOGIST

MEDICAL RESEARCH COUNCIL V.D. REFERENCE LABORATORY

The Wassermann reaction (W.R.) has long occupied a unique place among serological diagnostic tests because of the highly specific results obtained with an apparently non-specific antigen. Much work has been done since the inception of the test to determine the nature of the antigenic material in alcoholic extracts of beef heart, and Pangborn [1] has isolated a phospholipide called cardiolipin, which is an unstable acid and is therefore used in the form of its stable sodium salt. In crude tissue extracts it is probably present as either the potassium or sodium salt. Neither pure cardiolipin nor pure lecithin alone is active serologically, but in combination the mixture shows activity, and the addition of cholesterol enhances its sensitivity. The mixture of these three substances in well-defined proportions forms an antigen which has been widely used for the serodiagnosis of syphilis. By varying the proportions of the components, antigens suitable for both complement-fixation and flocculation techniques can be produced. Recent work on the properties and potentialities of cardiolipin has been summarised by Pangborn.[2]

The examination of large numbers of sera from widely differing types of patients, mainly in the United States, has produced favourable reports of the value of the cardiolipin antigens in the serodiagnosis of syphilis. They have been claimed to be both more sensitive, and at the same time more specific, than the relatively crude tissue-extract antigens now in common use, though cardiolipin antigens still produce some false positive reactions. Since the components of the antigens can be prepared in a high state of purity and their chemical constitution is fairly well known, the preparation of the antigen on a gravimetric basis may be attempted, but serological standardisation of each batch of antigen is essential, since batches of lecithin, and to a lesser extent cardiolipin, may vary in their antigenic activity. At present cardiolipin antigen has been adapted to many of the existing serological techniques, and there is no uniformity of opinion about which of these is the most satisfactory. The next serological conference to be held under the auspices of the World Health Organisation should give an opportunity for the controlled comparison of standard techniques by their originators, and should establish the place of cardiolipin in the serology of syphilis.

PRESENT INVESTIGATION

The present investigation was undertaken to compare the performance of cardiolipin antigen with the standard
Wassermann antigen prepared at the V.D. Refc
Laboratory, by the following method.

The muscle from the left ventricles of freshly killed o
freed from fat, epicardium, and endocardium. The n
is divided as finely as possible and then ground in a n
with a little powdered glass and successive portions of ab
alcohol to a total of 9 ml. of alcohol for each gramme of
muscle. The triturated muscle and alcohol are trans
to a flask closed with a tinfoil-covered cork and allow
stand in the dark at room temperature for five days
flask being shaken gently two or three times a day.
contents are then filtered through a no. 1 Whatman p
and the filtrate is placed in a refrigerator for twenty
hours and again filtered through a no. 1 Whatman p
The final product is stored in the dark at room tempera

The Wassermann technique used was a two-tube modi
tion of the Harrison-Wyler method developed by Pr

The cardiolipin antigen was made available thro
the courtesy of the New York State Departmen
Health, Division of Laboratories and Research. It
composed of cardiolipin 0·0175%, lecithin 0·0875%
cholesterol 0·3%, and was used at a dilution of 1 in
of saline.

Sera were tested in parallel on the same day; th
giving anomalous results were retested, usually a
an interval of three days. Before the second examina
a fresh specimen of serum was removed from the orig
blood-clot to reduce the possibility of technical er
to a minimum. The sera examined were drawn f
three sources:

Group I: routine sera from the Whitechapel Cli
A small series of sera from male cases of primary syphil
which the *Treponema pallidum* had been demonstrated
included in this group.

Group II: sera from a teaching hospital (The Lon
Hospital), of which about a third came from antenatal ca

Group III: sera sent to the V.D. Reference Laboratory
opinion. These included straightforward sera sent for c
firmatory testing as well as many "problem sera" which
given anomalous results in other laboratories.

In groups II and III we have had to depend on the b
clinical details supplied with the sera sent for testing;
that cases had to be assessed on these limited grounds.

In all, 5124 sera were examined in parallel with
two antigens. Those from the V.D. clinic and the teachi
hospital form a representative sample of sera likely to
encountered by any laboratory undertaking large nu
bers of Wassermann tests. It was found necessary
restrict the numbers of sera from the V.D. clinic whi
were tested in parallel with cardiolipin antigen to t
first 96 of each batch because of shortage of water-bat

Sera sent to the V.D. Reference Laboratory form
special group, since a proportion had previously giv
anomalous results in other laboratories. They we
included in the investigation because it was felt that th
would give a useful indication of the specificity
cardiolipin antigen.

DISCUSSION OF RESULTS

Cardiolipin antigen possesses several technical adva
tages by virtue of the high dilution at which it can
used. In this investigation it was used at the titre
1 : 150, the figure advised by the American worker
Titration of this batch (no. 72) by the optimal-proportio
method has since shown that the best results with th
Wassermann technique used are given at an even greate
dilution—1 : 400. However, at a dilution of 1 : 150
gives a very faintly opalescent solution which has n
more destructive action on complement than has salin
alone. The clarity of the antigen suspension as compare
with the well-marked opalescence of the cholesterolise
standard Wassermann antigen as issued from thi
laboratory when used at a dilution of 1 : 15 enhance
the clarity of negative tests in which the hæmolysis

truly "sparkling," and makes it easier to determine minor degrees of inhibition of lysis.

It can be said, however, that work by Price has shown that the standard cholesterinised Wassermann antigen gives its best performance at considerably higher suspensions than the 1 : 15 generally adopted, and a comparative series of tests between cardiolipin antigen and the standard antigen at its optimal titre are now being done.

RESULTS

Group I

The results obtained with routine sera from a V.D. clinic were as follows. Of 1982 sera tested, the tests agreed in 1898 (95%) and disagreed in 84 (5%). The tests were cardiolipin positive and routine W.R. negative in 80 sera as follows: untreated primary syphilis 4, treated syphilis 65, and non-syphilitic 11 (eight patients); and 4 sera from one patient (case 2) were cardiolipin negative and routine W.R. positive.

Clinical details were available regarding these V.D. clinic sera. Of the 80 sera where the cardiolipin antigen gave a positive result and the standard antigen a negative one 69 came from cases of syphilis. The remaining 11 sera were from eight patients, of whom one was a newborn child of a syphilitic mother, and passive transfer of reagin from the maternal circulation is a possible explanation. This case would therefore be included in the syphilitic group. There were five coloured patients from the West Indies or from West Africa; four of these had gonorrhœa and one non-specific urethritis. All of them omitted to attend for surveillance after treatment; so it is impossible to form any opinion about their syphilitic status. Moreover the possibility of positive serum tests as a result of childhood infection with yaws cannot be excluded. Since patients from West Africa and the British West Indies form only a minority of the patients in the clinic (1·9% of male admissions in 1948), their high proportion among this group of discrepancies may be significant. The remaining two patients (cases 1 and 2) are considered to have given biological false positive reactions with both antigens and are recorded in some detail.

Case 1.—A white man, aged 36, attended on Aug. 26, 1948, with gonorrhœa and was treated with penicillin 150,000 units. Tests of cure for gonorrhœa were satisfactory. Serological examinations gave the following results:

* Quantitative titre.

The possibility of an early syphilitic infection being aborted by the penicillin treatment for gonorrhœa cannot be excluded but is thought to be remote. The patient's wife was examined and no evidence of syphilis was found.

Case 2.—A white man, aged 44, had had syphilis in 1927, which had been treated with two courses of injections. There had been no further surveillance. On Nov. 1, 1948, he attended with a penile sore of two days' duration. Dark-ground examination for *T. pallidum* was negative on five occasions, and a Dmelcos skin test was negative. The patient was treated with sulphonamides. Serological examinations gave the following results:

This patient did not attend further, so no definite conclusion is possible. The rapid rise of the W.R. with standard antigen to a high titre and the subsequent fall towards negativity are noteworthy, as also is the fact that cardiolipin antigen gave a positive result with only one sample of serum from this patient.

Because six patients in this group of discrepancies are defaulting, it is impossible to assess their syphilitic status. Weighting the balance against cardiolipin, and assuming that all these patients were non-syphilitic, cardiolipin gave false positive reactions with 11 sera out of 1982 (0·5%); the true figure may well be below this.

The performance of the standard Wassermann antigen in this group was very good; the only times it gave positive results when the cardiolipin antigen gave negative ones were with 4 samples of serum from case 2.

In 59 cases of primary syphilis, proved by dark-ground microscopy, some of which are included in group I, the following results were obtained on testing the sera:

	Cases
Cardiolipin positive, routine W.R. positive	27
Cardiolipin negative, routine W.R. negative	25
Cardiolipin positive, routine W.R. negative	7
Cardiolipin negative, routine W.R. positive	0
Total ..	59

The foregoing figures for group I and the dark-ground positive group afford a basis for assessing the sensitivity of cardiolipin antigen. In the 59 dark-ground positive primary cases cardiolipin antigen gave 7 positive results when tests with the standard antigen were negative. In no case did the standard antigen give a positive result before cardiolipin. Though the number of patients is small, cardiolipin antigen does appear to detect primary syphilis earlier than does the standard antigen.

Though the dark-ground figures show that cardiolipin antigen is more sensitive than the standard antigen with sera of untreated primary syphilis, the other side of the picture is given by the 65 cases of treated syphilis in group I. Here the cardiolipin test was still positive, whereas the standard Wassermann had reversed to negative. It has been noted during the course of this work that this is the expected pattern of results in these cases, and cases of treated late syphilis have been observed where the cardiolipin test has remained positive for as long as eighteen months after the standard test and precipitation tests have reversed to negative. Subsequent follow-up of these patients for nine months after these positive cardiolipin results were obtained has not yet shown any other evidence of active syphilis.

It seems that the protracted seropositivity of treated cases is the price that must be paid for the high sensitivity required for the earlier detection of reagin in primary syphilis than is possible with standard antigen. The tendency of recent years has been to raise the sensitivity of serological tests for syphilis to the highest possible level compatible with the maintenance of specificity, and even deliberately beyond this level in the so-called presumptive or exclusion tests used for screening sera. In tests designed for the initial diagnosis of syphilis a very high level of sensitivity is eminently desirable, provided that it is not achieved at the expense of specificity. In the follow-up of treated cases of syphilis the high sensitivity of cardiolipin may prove an embarrassment to the clinician called on to interpret the results of tests in which it is used. For this type of work a simple standardised quantitative technique employing cardiolipin seems very necessary.

Group II

The results obtained with 2202 routine sera from a teaching hospital, consisting of 1417 from general medical and surgical cases and 785 from antenatal cases, were as follows. The tests agreed in 2184 (99%) and disagreed in 18 (1%). The tests were cardiolipin positive and routine W.R. negative in 8 sera from cases in which syphilis had been diagnosed, 8 sera (five patients) where the diagnosis had been other than syphilis, and 2 sera where the diagnosis was unknown. Of the 8 sera from cases diagnosed as syphilis, 7 were from cases of neurosyphilis and 1 from a woman with salpingitis who later became frankly seropositive. The 8 sera (five patients) from cases other than syphilis included 2 sera from a man with ophthalmoplegia and 1 from a case of intracerebral thrombosis, where syphilis might be expected to enter into the differential diagnosis; the remaining 5 sera came from patients with diagnoses of tuberculous bronchopneumonia, pneumonia (unspecified), and thyroid adenoma. Thus, where the diagnosis was known, the cardiolipin antigen gave 8 positive reactions in possibly non-syphilitic patients, or 0·36% of the total number tested. This figure is exaggerated by the fact that in two cases the serum was examined twice. In no case did the standard antigen give a positive result and the cardiolipin a negative one; this may be because the number of sera examined was relatively small. Of the sera examined in this group, 785 (35%) came from antenatal cases, and in these the results were identical whichever antigen was used: 6 sera (0·75%) were positive and the rest negative.

Group III

The results obtained with 940 sera sent to the V.D. Reference Laboratory for examination were as follows. The tests agreed in 853 (91%) and disagreed in 87 (9%). The tests were cardiolipin positive and routine W.R. negative in 36 sera from cases in which syphilis had been diagnosed, 4 sera from cases in which the diagnosis had been other than syphilis, and 4 sera from cases in which the diagnosis was unknown, making a total of 44. The tests were cardiolipin negative and routine W.R. positive in 7 sera from cases in which syphilis had been diagnosed, 33 sera from cases in which the diagnosis had been other than syphilis, and 3 sera from cases in which the diagnosis was unknown, making a total of 43.

Of the 44 sera in which the standard W.R. was negative while the cardiolipin W.R. was positive, 36 had come from cases diagnosed as syphilitic, the majority being old treated cases. Of the 4 sera from cases diagnosed as other than syphilis 2 were from newborn children of syphilitic mothers in whom reagin may have been transferred from the maternal blood-stream; these 2 sera might be included in the syphilitic group. The other 2 sera came from a case of keratitis and choroiditis and a case of gonorrhœa. Thus, where a diagnosis had been made, only 2 of 40 sera were from possibly non-syphilitic patients—i.e., 0·2% of the total sera.

Of the 33 sera where the standard W.R. was positive and the cardiolipin W.R. negative in cases diagnosed as other than syphilis, 5 came from cases of gonorrhœa, 1 from a case of keratitis, and 2 from a man with a chronic penile sore. Where a diagnosis had been made, the standard antigen gave positive reactions with 33 possibly non-syphilitic sera—i.e., 3·5% of the total sera.

These sera cannot be considered as routine specimens, for many of them had given anomalous results in other laboratories and they included many "problem sera." Nevertheless, the superior performance of cardiolipin antigen over the routine antigen is conspicuous, and the cardiolipin W.R. might prove a useful additional means of investigating possible false positive sera.

SUMMARY

Cardiolipin antigen has been compared with standard Wassermann antigen by the parallel testing of 5124 sera, using a modified Harrison-Wyler technique. The sera included routine specimens from a venereal diseases clinic, a general hospital, antenatal clinics, and sera sent for opinion to the V.D. Reference Laboratory.

Cardiolipin antigen was appreciably more se than the standard antigen, detecting a higher prop of cases of early primary syphilis, and remaining p in treated cases of syphilis after other tests had reversed to negative.

In testing the special sera sent to the V.D. Ref Laboratory cardiolipin was more specific than standard antigen. In the other two groups (V.D. and general hospital) this advantage was not appa

CHLOROMYCETIN IN SCRUB-TYPHU

From a Military Hospital in Malaya

THE first clinical trial of natural 'Chloromyc (chloramphenicol) in scrub-typhus was made b American research unit working from the Institut Medical Research in Kuala Lumpur in 1948. The val chloromycetin was unequivocally established (Sma al. 1948), and a few months later similar results obtained with synthetic chloromycetin (Smadel 1949).

Attention has since been directed towards redu of dosage, owing to the cost and scarcity of chloromy In their earlier cases Smadel et al. (1948) gave an i dose of about 50 mg. per kg. of body-weight, follow 0·2–0·3 g. every 2–4 hours for a variable period. Inc ing experience enabled them to shorten the course, their last seven patients received about 6 g. in 24 h with equally satisfactory results. Smadel et al. (used a still smaller dosage of synthetic chloromyc two cases responded to 4 g. and 5 g. given in onl hours.

In March, 1949, therefore, at the suggestion of Charles Bailey, who was then leading the scrub-ty research unit, we undertook to reduce our stan course to a single dose of 3 g. This dose has now used in sixteen consecutive unselected cases of s typhus (table I) in Service personnel between M and July. All the patients were men of military age youngest being 17 and the eldest 31; British, Gurk and one Chinese are included. The infections acquired in various localities throughout North Central Malaya; hence, if different strains of *Ricke tsutsugamushi* exist in the Malay peninsula, our ex ence is not likely to be restricted to one variety on

important point in planning a dosage schedule of eral application. Chloromycetin was given at various ges of the disease, once as early as the 4th day, and ce as late as the 21st.

CLINICAL FEATURES AND DIAGNOSIS

Scrub-typhus has a case-mortality which has varied om 0·6 to 35·3% in different epidemics (Philip 1948) d in Malaya in 1940 was about 15% (Lewthwaite and voor 1940). Its natural course in non-fatal cases is wards resolution by rapid lysis after a febrile period nging from 12 days in mild cases to 25 or more in those mplicated by bronchitis or bronchopneumonia. The inical syndrome is marked by some or all of the following atures: eschar, maculopapular erythematous rash, cal and generalised enlargement of lymph-glands, njunctival suffusion and injection, a characteristic bloated" facial appearance, and, almost invariably, vere headache and intense general malaise. Complica- ons may be pulmonary, cardiac, or neurological.

In only two of the present cases was it possible to stablish the diagnosis beyond dispute by recovery and emonstration of the causal rickettsia after inoculation f a saline suspension of the patient's defibrinated red lls into mice. Nevertheless, seven patients had an mistakable eschar with well-marked regional lymph- enopathy, and in all the cases fever, rash, generalised mphadenopathy, facial appearance, and subjective nptoms in various combinations were enough to point cisively to the diagnosis. Confirmation was provided the Weil-Felix reaction. Lewthwaite gives as his inion that agglutination of *Proteus OXK* to a titre in 125 may be regarded as evidence of tsutsugamushi ection, but points out that titres as high as 1 in 480 ve been recorded in leptospirosis (Lewthwaite and voor 1940). Personal experience leaves us in no doubt at non-specific titres as high as 1 in 400 are regularly ncountered. It will be seen, however, that in twelve of he present cases the titre rose to 1 in 1600 or more, and his level was maintained until well into convalescence; e consider that these figures can be accepted as diag- nostic. In three other cases, where the highest titre was in 800, we regard them as strongly suggestive. The tre of 1 in 400, which was the maximum recorded in remaining case, is not inconsistent with the diagnosis, d the clinical picture here was typical in every way.

TREATMENT

All the patients, irrespective of age, race, weight, or he severity or duration of the disease, received a standard ose of 3 g. of synthetic chloromycetin, given as twelve ·25 g. tablets, not crushed or modified in any way. ost of the patients experienced nausea immediately fter receiving the tablets, but all retained them without due difficulty. Case 12 received a further 2·25 g. spread er 30 hours, and is reviewed in greater detail below. his patient and two others also received a course of enicillin, in view of the intensity of their pulmonary ymptoms. All the British patients, and some Asians, ho were taking suppressive antimalarial drugs before dmission, received 0·1 g. of mepacrine daily as a routine hroughout their stay in hospital. Any other treatment iven was purely symptomatic—e.g., analgesics for eadache and muscular pain.

ILLUSTRATIVE CASE-RECORDS

Case 9.—A Gurkha soldier, aged 24, who had been on jungle operations for the previous fortnight, was admitted on May 13, 1949, with headache, cough, and fever. These symptoms had first been noted 10 days before and had become progressively more severe; he had also developed a septic spot under the right armpit, with swollen and tender glands above it.

On examination, the patient was moderately ill; temperature 101°F, pulse-rate 90 per min. There was no conjunctival suffusion or injection, and no rash. In the right axilla there was a small black scab about 7 mm. by 2 mm. overlying an ulcer of similar size, with the typical appearance of a primary eschar. The regional lymph-nodes were much enlarged and tender, and there was a lesser degree of generalised lymphadenitis. No evidence of cardiovascular, respiratory, or nervous involvement was found.

Investigations.—Blood slides showed no malarial parasites, the Widal reaction was negative, and agglutination tests for brucellosis were also negative; the white-cell count was 5000 per c.mm., with a normal differential count. The Weil-Felix reaction (May 14) was negative with *Proteus OX19* and positive to a titre of 1 in 400 with *OXK*. Mouse inoculation was not attempted.

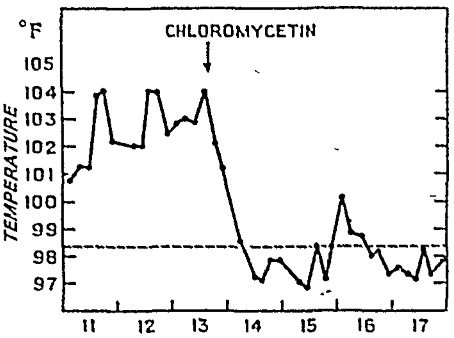

Fig. 1.—Chart of case 9.

Progress and Treatment.—During the next 2 days the patient's temperature ranged between 102° and 104°F; there was no essential change in his general condition. On May 16 at 2.30 P.M. he was given 3 g. of chloromycetin. At 6 A.M. on the 17th—i.e., $15^{1}/_{2}$ hours later—his temperature was normal, and he had lost all his symptoms and felt perfectly well. The lymph-glands were still enlarged but were no longer tender, and during the subsequent week they returned to normal size and the eschar healed. On May 20 the patient's serum agglutinated *OXK* in a dilution of 1 in 1600. He was transferred to convalescence on June 7.

Case 14.—A British soldier, aged 20, who had been on operational duties in the jungle, was admitted on June 20, 1949, with frontal headache, sore eyes, diarrhœa, and cough. The symptoms had started 9 days previously and were associated with nausea, vomiting, and insomnia. A full mepacrine course was instituted 4 days before admission, but there had been no change in symptoms or reduction in temperature.

On examination the patient looked toxic and ill; his temperature was 104·6°F and his pulse-rate 110 per min. His skin was hot and dry, and the conjunctivæ were injected. There was some faucial and pharyngeal inflammation. No rash or eschar was observed; the axillary and inguinal lymph-glands were slightly enlarged and tender. Generalised rhonchi were audible throughout the lungs, and there were a few basal râles, but no other abnormality was found in lungs, heart, abdomen, or central nervous system.

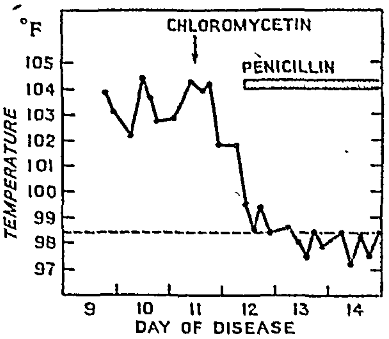

Fig. 2.—Chart of case 14.

Investigations.—Blood slides were negative for malarial parasites; the white-cell count was 7800 per c.mm., with a normal differential count; the Widal reaction was negative. The Weil-Felix reaction (June 21) was positive with *OX19* to a dilution of 1 in 50 and with *OXK* to a dilution of 1 in 400.

Progress and Treatment.—There was no essential change in the patient's condition on June 22, and he was given 3 g. of chloromycetin at 12.30 P.M. His temperature fell rapidly and by 2 P.M. on the 23rd—i.e., $25^{1}/_{2}$ hours later—it had become normal and he felt very much better. The lymph-glands, though still enlarged, were no longer tender. In view of the persistent signs of pulmonary involvement, the patient was given 50,000 units of penicillin 4-hourly for 5 days. On June 25 the Weil-Felix was positive with *OX19* to a titre of 1 in 200 and with *OXK* to 1 in 1600; the patient was afebrile and felt well, though there was still some residual bronchitis. On July 5 the lungs were clear on auscultation and the lymphadenitis had completely resolved. A coarse grating friction sound developed in the region of the right nipple, but the patient remained afebrile and symptom-free and was ultimately transferred to convalescence on July 26.

RESULTS

Mortality.—There were no deaths.

Effect on Temperature and Pulse.—In eleven cases the pulse-rate and temperature fell to normal within 18 hours and the temperature did not subsequently exceed 100°F at any two consecutive readings (temperatures were recorded 4-hourly). Figs. 1 and 2 show charts of typical cases from this group. In three cases a further 24 hours elapsed before the temperature settled completely, whereas two others required 54 and 72 hours.

Effect on Physical Signs.—The rash disappeared with the fall in temperature, except where there was petechial staining of the skin; this faint brownish discoloration persisted until well into convalescence. The primary ulcer lost its inflamed appearance the day after chloromycetin had been begun and healed as rapidly as any simple aseptic abrasion. Adenitis became painless within 24 hours or so, but enlargement of the glands subsided very gradually and was often still detectable at the time of discharge from hospital. Conjunctival injection and suffusion cleared in 24 hours.

Effect on Symptoms.—This was perhaps most striking of all. Headache and malaise were relieved even before the temperature returned to normal, and the change in the patient's appearance and demeanour was remarkable; men who one day were thoroughly miserable and apathetic by next morning looked bright and well and asked to be allowed up. Nevertheless, weakness, lassitude, giddiness, and other manifestations of postfebrile debility often appeared if convalescence was unduly hurried.

Effect on Complications.—Two patients with severe bronchitis and one with clinical bronchopneumonia were treated with penicillin, making it difficult to assess the part played by chloromycetin. In all three the pulmonary condition began to improve soon after the administration of chloromycetin—i.e., within 2 or 3 days. One patient developed a symptomless pleural rub during convalescence; radiography of the chest did not reveal any parenchymatous lesion, and the pleurisy resolved uneventfully. Only one patient showed significant evidence of cardiac involvement, in multiple extrasystoles, but the irregularity had largely disappeared before chloromycetin was given, and after treatment no clinical evidence of myocarditis was found. In many patients, especially those treated late in the disease, even gentle exercise caused disproportionate tachycardia until well on in convalescence. This is no doubt a manifestation of functional rather than structural disorder; it is none the less well established that fatal cases of scrub-typhus may show histological evidence of an intense myocarditis. One would not expect chloromycetin to influence pre-existing myocardial damage, and we have therefore continued to enforce a protracted convalescence on the assumption that time must be allowed for the repair of a structural cardiac lesion. On all other counts most of the patients could have been discharged within a few days of treatment.

Relapses.—Every patient has been under our own observation for at least 19 days after treatment, and at a convalescent depot for at least another fortnight. Only in case 11 was anything suggesting a relapse observed; this patient had an irregular fever rising to 101–102°F associated with headache, which lasted 10–16 days after treatment. It is noteworthy that he was not treated until the 21st day of his illness. One patient had a low-grade fever accompanied by gastro-enteritis, which started on the 3rd day after treatment and responded to sulphaguanidine.

Ultimate Disposal of Patients.—All patients who have completed their convalescence have returned to full military duty. In pre-chloromycetin days 25% of those who recovered from scrub-typhus had eventually to be invalided (*Lancet* 1949), and this result is therefore regarded as of real significance.

Failures.—As mentioned above, in case 12 the response to a single dose of 3 g. of chloromycetin could be regarded as suboptimal; this man's temperature chart is shown in fig. 3, and his case-record was as follows:

Case 12.—A British soldier, aged 19, who had been on jungle operations up to the onset of his illness, was admitted on June 7, 1949, with headache, fever, and general malaise, which had first been noticed 5 days before; 2 days before admission he had developed an unproductive cough.

On examination he was flushed and looked ill; his temperature was 104°F, and his pulse-rate 108 per min. There was slight cervical and axillary lymphadenopathy. No rash was observed, but behind the left knee, lying in the line of the skin folds, was a punched-out ulcer about 6 mm. by 4 mm. covered with a black scab, surrounded by a pink areola, and having the *typical appearance of a primary eschar.* Auscultation of the lungs revealed numerous adventitious sounds, including crepitations, at the left base. No abnormality was found in heart, abdomen, or central nervous system.

Investigations.—Blood slides were negative for malaria parasites; the white-cell count was 5400 per c.mm., with a normal differential count. The Weil-Felix reaction (June 8) was positive to 1 in 25 with *OX19* and to 1 in 400 with *OXK*.

Treatment and Progress.—In view of the pulmonary condition 40,000 units of penicillin 4-hourly was started at 6 P.M. on June 8. On June 9 the patient was more prostrated and lay inertly in bed with eyes half-closed; his facial appearance exhibited the blend of "bleariness" and apathy characteristic of the severe case of scrub-typhus. His lungs were clearer on auscultation, but his respiration-rate had risen to 38 per min. Blood taken at this time for mouse inoculation gave negative results. The patient was given 3 g. of chloromycetin at noon, but at 6 P.M. his temperature was 104°F and pulse-rate 112 per min.; his general condition showed no improvement, and his respiration was almost entirely abdominal. At 10 P.M. his condition was worse, and his respiration-rate had risen to 56 per min. He was given 1 g. of chloromycetin at 10.30 P.M. followed by 0·25 g. at 3 A.M. and 7 A.M., and 0·5 g. at 11 A.M. on June 10. By this time his condition was very much better, his temperature being down to 99·2°F and respirations to 28 per min. His liver and spleen were palpable 1 finger-breadth below the costal margin on inspiration. He was given a final dose of 0·25 g. of chloromycetin at 3.30 P.M. Thenceforward his convalescence was uneventful. The Weil-Felix reaction on June 11 was negative with *OX19* and positive to 1 in 800 with *OXK*. By June 17 the lungs were clear on auscultation, the liver and spleen were impalpable, and the patient was finally discharged on July 10.

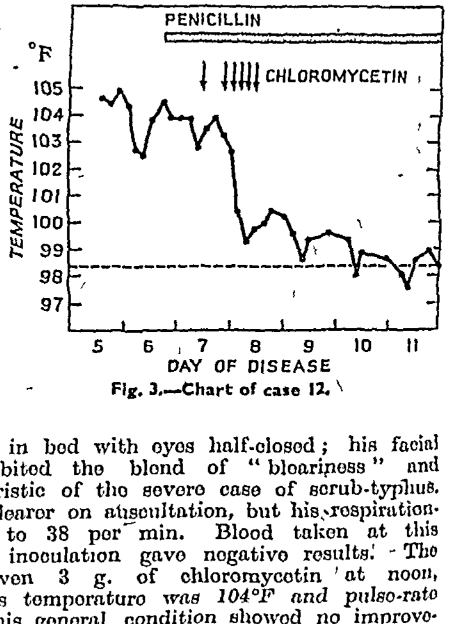

Fig. 3.—Chart of case 12.

Toxicity of Chloromycetin.—Other than slight and transient nausea, no toxic effects have been observed which could be attributed to chloromycetin.

Comment.—Smadel et al. (1948), whose series is the only one so far available for comparison, have tabulated

TABLE II—COMPARISON OF RESULTS WITH THOSE OF SMADEL ET AL. (1948)

—	Smadel et al.	Present series
No. of patients	25 (18 male, 7 fem.)	16 males
Day after onset when treatment was begun	3–11 (av. 6·2)	4–21 (av. 11·3)
Last febrile day of illness	4–12 (av. 7·5)	5–22 (av. 13·0)
Duration of fever (hr.) after treatment begun	10–96 (av. 31)	12–72 (av. 26·0)
Day after onset when discharged from hospital	9–28 (av. 19·2)	26–53 (av. 37·0)
Complications	0	1 (dry pleurisy)
Deaths	0	0

their results as in table II. where those of the present investigation are also recorded. The longer period, in our series, from the onset of the disease to discharge from hospital is, as explained above, due to the policy of retarding convalescence to allow for the repair of any possible cardiac damage. The greater delay in starting treatment is related to the difference in composition between the two groups, and, since there is no significant discrepancy between the results obtained, is of no further relevance.

DISCUSSION

Chloromycetin is now in daily use for the treatment of scrub-typhus in Malaya, and the brilliant promise of the original report of Smadel et al. (1948) has been amply fulfilled. The remarkable therapeutic response which we describe here is coming to be accepted as a commonplace, and we show that this response can be as rapidly and fully evoked with a single dose of 3 g. of chloromycetin as with the heavier and more protracted dosage hitherto used. This contention is based on a consideration of the mortality-rate, subjective and objective response, relapse-rate, incidence of complications, and ultimate disposal. In the single case where this dose seemed inadequate the patient was very severely ill and had developed a complicating bronchopneumonia before chloromycetin could be given. He would probably have recovered without additional chloromycetin, but it would clearly have been unjustifiable not to give it. Nevertheless even in this type of case treatment can be started with a single dose of 3 g., for the response is normally so rapid that the necessity, if any, for more chloromycetin will be apparent within 10–12 hours—i.e., before any significant time has been lost. Clearly, further reduction in dosage may be found possible, but here already is a treatment of exceptional simplicity, efficacy, and general applicability for a crippling and lethal disease. The most severe attack of scrub-typhus can be dramatically and consistently terminated within a few hours, and the dangerously ill patient rapidly made afebrile and symptom-free with one dose of a drug which is devoid of toxic effects and can be administered by the most unskilled. This is surely one of the most remarkable achievements in the whole field of chemotherapy.

The advent of chloromycetin makes early diagnosis more important than ever. Other fevers encountered in scrub-typhus areas may have a similar onset, and the distinction from them is sometimes difficult to make on clinical grounds alone. The Weil-Felix reaction may not give a conclusive answer until the middle of the 2nd week, and the results of mouse inoculation are not available for a fortnight; hence these tests are of value only in retrospect. When chloromycetin is more plentiful diagnostic uncertainty will no doubt seem less important: in existing circumstances we have been acutely aware of the lack of a reliable means of establishing the diagnosis in the first few days of illness.

SUMMARY AND CONCLUSIONS

Sixteen cases of scrub-typhus in British, Gurkha, and Chinese soldiers in Malaya are reported.

Each patient was given one dose of 3 g. of synthetic chloromycetin: fifteen responded fully and required no further treatment.

One patient did not improve within 10 hours, and was given an additional 2·25 g. of chloromycetin, after which he made a rapid recovery.

In the light of these results it is suggested that the routine treatment of scrub-typhus need consist of no more than a single dose of 3 g. of chloromycetin. If, however, obvious improvement is not apparent within 10–12 hours an additional dose of 1 g. should be given, followed by 0·25 g. 3-hourly to a total of about 6 g.

We wish to acknowledge with gratitude the unstinted advice and assistance we have received from the staff of the Institute for Medical Research, Kuala Lumpur, and in particular from Dr. J. W. Field, the director, and Dr. R. Green, the senior bacteriologist; we are also indebted to them for our chloromycetin. Our thanks are due to the Director of Medical Services, FARELF, for permission to publish this article.

THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, LONDON

IN August, 1948, Swenson and Bill reported a clinical and radiographic study of Hirschsprung's disease, and in their paper of October, 1949, they give credit to Neuhauser for the radiological findings (Swenson, Rheinlander, and Diamond 1949). They demonstrated a "spastic" segment of colon distal to the dilated part and concluded that this obstructive narrowing is responsible for the megacolon. They introduced resection of the abnormal segment—rectosigmoidectomy—as a new rational treatment.

Our first communication on this subject was published in THE LANCET of Jan. 1, 1949, just a year ago. The purpose of the present paper is to record the results of a clinical and radiological follow-up for over a year of the previously published 12 cases treated by rectosigmoidectomy; to report a further 14 cases; and to discuss the pathological findings in a total of 28 specimens.

It may perhaps be useful to summarise our previously published findings. Clinical, radiological, and pathological evidence was produced for a new conception of the organic ætiology of Hirschsprung's disease, thus separating it from idiopathic megacolon. Hirschsprung's disease, a congenital condition, may present as acute intestinal obstruction in the newborn, and, if not fatal, it runs a chronic course with superadded acute attacks. Medical and surgical procedures, other than colostomy, failed to produce more than transient relief, since they were aimed at treating the hypertrophied dilated "megacolon." Distal to this, however, a narrow segment was invariably demonstrable by careful radiological technique. Clinical evidence was produced which placed the site of obstruction in this relatively unimpressive

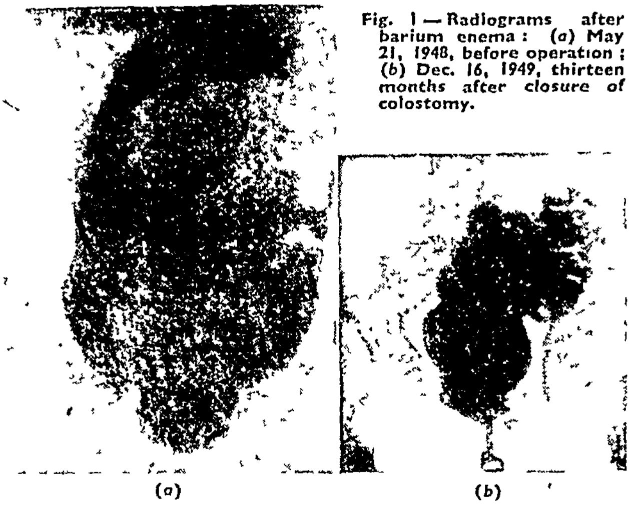

Fig. 1—Radiograms after barium enema: (a) May 21, 1948, before operation; (b) Dec. 16, 1949, thirteen months after closure of colostomy.

distal segment. Histological examination of the entire intestinal tract in 2 fatal cases revealed complete absence of ganglion cells from the intramural plexuses of this narrow distal segment. It was postulated that this would impair coordinated propulsive movement and lead to secondary hypertrophy and dilatation of the bowel proximal to the site of the lesion. A new surgical technique for removal of the abnormal distal segment—rectosigmoidectomy—was used in 12 children, and the pathology was uniformly confirmed. A preliminary follow-up of 11 cases for periods of one week to three months showed encouraging results.

FOLLOW-UP OF FIRST 12 CASES

Clinical Findings

The follow-up period was calculated from the date of final closure of the colostomy after rectosigmoidectomy. In the 12 cases originally described, the clinical course has been satisfactory during the last twelve to fifteen months. All the children are in excellent general health. They have regular spontaneous bowel actions, 8 without medicines and 4 with mild aperients. One child had his bowels open only every fourth day, but he is in good health and there is no evidence of any residual organic obstruction (fig. 1). Seven children are completely free from abdominal distension, and 5 have occasional distension which is relieved by spontaneous passage of flatus. The motions are still somewhat narrowed in 2 cases, unformed in 2, and normally shaped and formed in the remainder. Six older children appear to have normal rectal sensation, and respond at will to an apparently normal urge to defæcate. One child, who had severe bladder palsy for five months requiring cystostomy, is now cured. Two children had transient postoperative urinary retention, one minor fæcal incontinence, and one a mild form of narrowing at the site of intestinal anastomosis. All the patients are now continent of urine and fæces, and there are now no complications in this series.

It is appreciated that the final judgment of a new form of treatment in a chronic disease will require many years' follow-up.

Radiological Findings

All the 12 original cases show radiological improvement. Generally, they were examined postoperatively at five to nine months, and again at twelve to fifteen months after closure of the colostomy.

Straight films of the abdomen show a little more than average amount of gas in the colon and no excess of fæces. Barium enemata were performed by the technique previously reported. Only the segment of colon adjacent to the anus was filled, this being the part which before operation was adjacent to the aganglionic segment.

In 3 cases this part of the colon was almost within normal limits. In 7 cases the colon, while much reduced in size, was still above normal diameter (fig. 2). Haustrations had not reappeared, and where the gut was not distended by gas or emulsion it had a wrinkled and folded appearance. It follows that owing to the prolonged distension and hypertrophy, the volume of the full colon and the surface area of the collapsed colon are both greater than normal. In 2 cases, where the preoperative examination was made in infancy and only moderate distension demonstrated, the absolute size of the bowel shows little change postoperatively, but relative to the size of the child it approximates more nearly to normal.

Immediate postevacuation films, taken before and after operation, were thought to reveal no significant physiological information.

Further observation will be necessary to determine the end point of the regressive changes which are apparent on comparison of preoperative with first and second postoperative examinations.

THE NEXT 14 CASES

During the past twelve months a further 14 rectosigmoidectomy operations have been performed for Hirschsprung's disease. The last stage of the procedure —closure of the colostomy—has not been reached in one case and was so recent in 2 cases that they have been excluded from the follow-up analysis. Nine children were followed up for periods ranging from three to eleven and a half months. Six of these appear to be making satisfactory progress similar to that of the earlier group. Two have developed anastomotic strictures which require regular dilatations, but in spite of this they have regular spontaneous bowel actions and progress as well as the 6 mentioned above. One patient is much improved, and has daily spontaneous evacuations, but abdominal distension develops in the evenings and subsides spontaneoulsy after passage of flatus during the night; this is possibly due to the failure at operation to remove enough of the pathological segment at the lower end of the rectum.

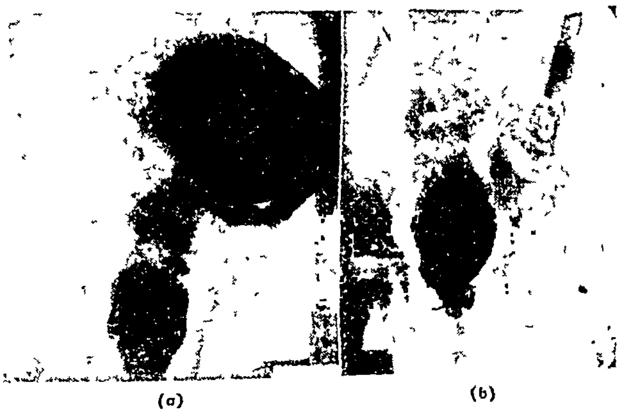

Fig. 2—Radiograms after barium enema in the case with long narrow segment illustrated by Bodian et al. (1949): (a) March 9, 1948, before operation; (b) Dec. 16, 1949, fifteen months after closure of colostomy. Rectosigmoidectomy was performed on July 29, 1948, and the colostomy was closed on Sept. 6, 1948.

There were 2 deaths. An infant, aged 1 year, died at the end of the rectosigmoidectomy operation which was complicated by severe and protracted anæsthetic convulsions. The other fatality was in a boy aged 7½ years who had previously had nine operations, including sigmoid colectomy, for relief of obstruction and closure of fistulæ. He died on the third postoperative day from peritonitis and ischæmic necrosis at the suture line.

In this last group of 14 rectosigmoidectomy operations, 2 children have previously had sigmoid colectomies performed. One was the fatal case just described, and in the other the descending colon was successfully mobilised and anastomosed to the lower end of the rectum after excision of the aganglionic segment.

One child had had a left hemicolectomy. Rectosigmoidectomy and anastomosis of the transverse colon to the lower end of the rectum were successful. He now has regular unformed spontaneous motions, with only occasional transient abdominal distension, and is in good health eleven and a half months after the closure of his colostomy.

Postoperative follow-up reveals a most encouraging improvement in the general condition of the children and the appearance of normal bowel habits. The complications are due to technical errors which, we hope, have been overcome by slight alterations in procedure.

PATHOLOGY

Our material to date consists of 28 consecutive cases. The first 2 were necropsies in 1947, previously reported, and 26 specimens were received after rectosigmoidectomy operations. In addition, necropsies were performed on the 2 fatal surgical cases. Histological examination was carried out by the technique previously described, and in all fatal cases consecutive blocks were taken from œsophagus to anus.

The histological findings which were reported a year ago have been amplified and uniformly confirmed. Complete absence of ganglion cells from the intramural plexuses was noted in the most distal segment of large intestine, which varied from 4 to 26 cm. in length and comprised the distal "narrow segment" frequently extending for 1–5 cm. into the transitional dilated zone (fig. 3). The distal extremity of the aganglionic gut was the line of excision in the rectum or anal canal in all surgical specimens, and the anocutaneous margin in all autopsies. The proximal extremity varied and lay either at the rectosigmoid junction or anywhere in the sigmoid or descending colon, the splenic flexure being the highest level in our series. Extensions of the aganglionic segment to the hepatic flexure and even to the terminal ileum have been reported elsewhere. Except for a short transitional zone with scanty and small ganglion cells, normal ganglia were found in all blocks proximal to it. Complete section of the intestinal tract in our 4 necropsy cases gave the same result.

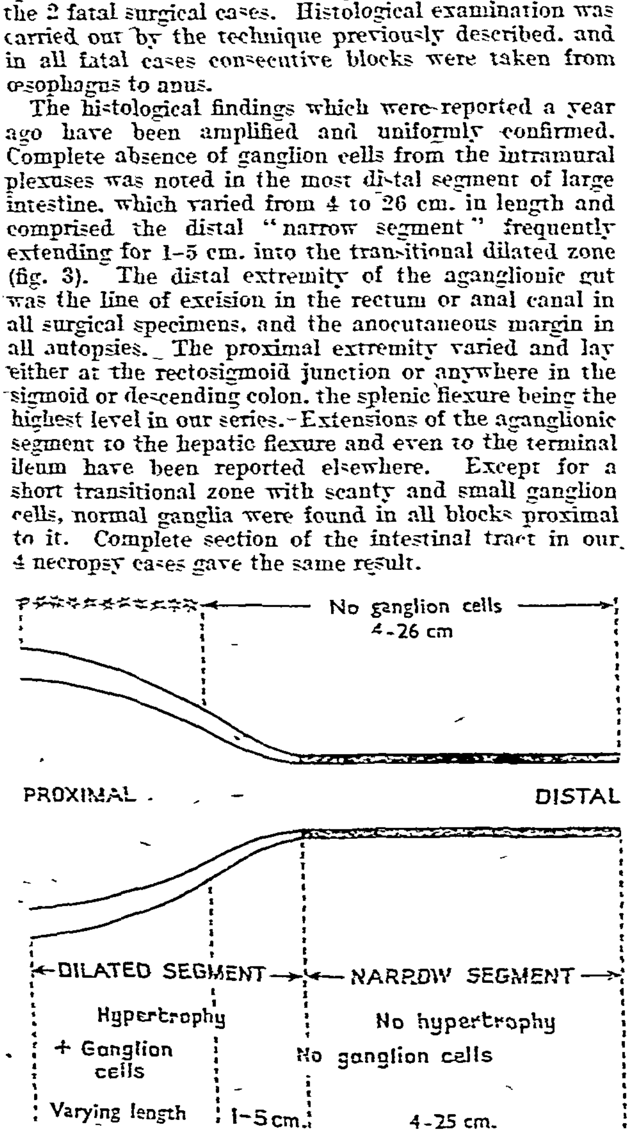

Fig. 3—Pathology of 28 cases of Hirschsprung's disease with narrow segment.

A striking feature in the aganglionic segments was the finding of numerous nonmedullated nerve bundles with supporting cells in the customary sites of the intramural autonomic plexuses. These bundles were densely woven and surrounded by a definite connective-tissue sheath. They varied considerably in size and were sometimes very conspicuous. They constituted as characteristic a feature of the abnormal segments as the absence of ganglion cells, and could not be found in any of our previously reported 11 control cases. The origin of these nerve-fibres is not known.

DISCUSSION

The absence of intramural ganglion cells is interpreted as the principal lesion in Hirschsprung's disease, and absence of peristaltic movement is its functional manifestation.

Some important new physiological observations have been made by Swenson, Rheinlander, and Diamond (1949), who have studied colonic motility by means of a multiple balloon technique. In 8 patients with Hirschsprung's disease they have recorded strong peristaltic waves in the dilated and hypertrophied colon, but the peristalsis did not enter the narrow distal segment, which exhibited increased tonus.

We find it difficult to explain in terms of current physiological teachings the three observed facts of absent intramural ganglion cells, absent peristalsis, and increased tone in the affected segment. In our previous paper we tried to correlate the pathological and clinical findings with the autonomic innervation of the bowel, but we now prefer not to offer any such interpretations.

Removal of the pathological segment by rectosigmoidectomy appears to be a rational treatment of Hirschsprung's disease, and this contention is supported by our own follow-up and by the excellent therapeutic results of Swenson, Rheinlander, and Diamond (1949). Operations in their 34 patients have resulted in one postoperative death and in apparently complete cure in the remaining 33 cases, who have been followed for periods up to two years. Re-examination by barium enema has demonstrated return of the colon to approximately normal size and contour by the third postoperative month. In 3 patients normal colonic peristalsis was demonstrated postoperatively by balloon studies.

We conclude from the histological findings in our 28 consecutive cases that these structural changes are characteristic of Hirschsprung's disease and constitute its uniform pathology. In this respect we go further than Swenson, Rheinlander, and Diamond, who in their paper of October, 1949, describe similar changes in 7 out of their total of 34 cases but do not suggest "that this occurs in all cases of congenital megacolon." Unfortunately they do not describe the histological findings in their first 26 cases, which were reported in August, 1949 (Swenson, Neuhauser, and Pickett, 1949). One of their specimens displayed a pathological variant which has been reported once before (Tiffin *et al.* 1940)—namely, segmental absence of ganglion cells in part of the sigmoid colon with normal ganglia above and below. We have not yet encountered this interesting but probably rare pathological variant of Hirschsprung's disease.

Another valuable pathological study of 11 cases of Hirschsprung's disease was published by Whitehouse and Kernohan early in 1949. Their findings are essentially the same as ours, and their results and our own may be taken as mutually confirmatory.

SUMMARY

A new ætiological conception of Hirschsprung's disease has been developed over the last two years, and a rational treatment devised. The observed facts are absence of intramural ganglion cells, absence of peristaltic movement, and increased tone in an apparently grossly normal segment distal to the dilated and hypertrophied colon.

This distal "narrow" segment has been removed by rectosigmoidectomy in 26 children.

Postoperative follow-up for twelve to fifteen months of the first 12 previously reported cases shows a most encouraging improvement in the children's general condition and a return to normal bowel habits. Radiological examinations also indicate considerable regressive changes in the volume of the full colon and the surface area of the collapsed colon.

Rectosigmoidectomy has been done in a further 14 patients during 1949, with 2 deaths. Nine children are making satisfactory progress comparable with the former group, notwithstanding some technical errors resulting in complications in 3 cases. The last 3 operations were too recent to be evaluated.

Histological examinations in 28 consecutive cases of Hirschsprung's disease have revealed two striking structural changes in the distal "narrow" segment of bowel—absence of intramural ganglion cells, and the presence of abnormal nerve bundles in the customary sites of the intramural plexuses.

These changes are thought to be characteristic of the condition.

We are glad to acknowledge our indebtedness to the consultant staff of the Hospital for Sick Children for their cooperation and permission to include their cases in this report.

PASSAGE OF AN INTESTINAL TUBE PER ANUM

George Frank
M.D. Budapest
ASSISTANT, III SURGICAL CLINIC, UNIVERSITY OF BUDAPEST

The following experience with intestinal intubation, though not unique, seems unusual enough to be recorded.

A woman, aged 28, was admitted to hospital on Dec. 11, 1948, with colicky abdominal pain which had continued for three days, during which she had passed neither stool nor flatus and had vomited several times. In the previous year she had twice undergone right posterior pyelotomy for removal of calculi; and at the second operation, three weeks previously, right-sided nephropexy had been performed. *Urological examination at that time had revealed on the opposite (left) side the presence of two ureters which led by a common ureter into the bladder.*

On admission, the patient's general condition was good; she was afebrile. The tongue was somewhat dry. In the abdomen there was meteorism, but no muscle-guarding; occasionally, especially on the left side, the bowel was palpable in spasm; on auscultation numerous borborygmi were heard. The urine was normal; non-protein nitrogen 40 mg. per 100 ml. blood.

It was decided not to operate. A Cantor intestinal tube was introduced nasally; and eight hours later X-ray examination showed that the tip of the tube had passed far into the jejunum. During the first twenty-four hours no more than 500 ml. of intestinal contents was withdrawn by permanent suction through the tube. *The cramp-like pain and vomiting continued*; and saline and glucose were infused intravenously.

On Dec. 12, twenty-four hours after the tube was introduced, the abdominal pain became still more severe, notably on the *left side in the region of the descending colon.* The sigmoid colon was palpable in severe spasm, during which intestinal fluid gushed from the end of the Cantor tube. Soon afterwards, to our astonishment, the balloon end of the tube appeared at the anus. *The whole tube was then drawn without difficulty through the anus.* Thereafter the ileus ceased, *and the patient passed stool and flatus. For a day or two she continued to vomit and to have abdominal pain*, but this grew milder and soon ceased. Further investigation of the alimentary tract and gall-bladder brought to light no further clue to the cause of the ileus. Three months later the patient was symptom-free.

The Cantor tube was 10 ft. long, and when the balloon-end passed the anal ring there was still 3 ft. 3 in. protruding from the nose; thus the length in the nasal and alimentary tract was 6 ft. 9 in.

After death, the bowel appears longer than it actually is in life; and evidently in this case the normal in-vivo length of the small intestine was much reduced by *concertina-like spasm, which may have been aggravated by* the mechanical irritation of the tube itself. Thus, it is perhaps unwise to insert through the nose or mouth more than 5–6 ft. of an intestinal tube.

A SWALLOWED BOUGIE

James A. Ross
M.D. Edin., F.R.C.S.E.

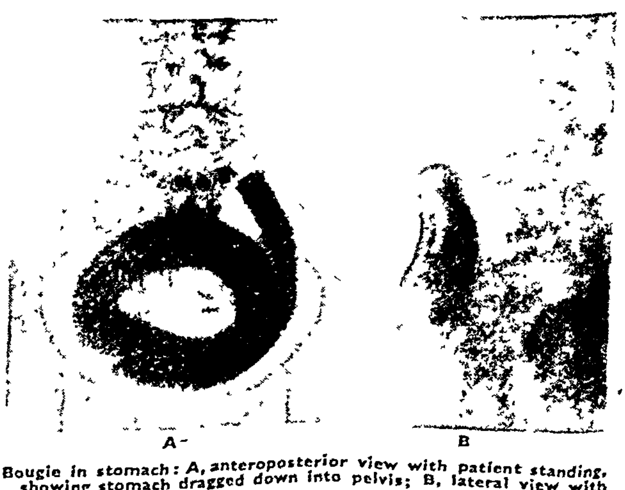
In the treatment of achalasia of the cardia the habitual passage of a Hurst's mercurial bougie is "both simple and effective."[1] After the unpleasantness of the preliminary trials, the patient becomes accustomed to swallowing the heavy tube. In this, however, as in other things, familiarity may breed contempt, with unpleasant consequences, as the following case-history shows.

On June 15, 1949, a married woman, aged 59, was admitted to the Royal Infirmary, Edinburgh, under the charge of Mr. R. Leslie Stewart, with a history of having swallowed her mercury bougie about three hours before.

She had been in the *Chalmers Hospital, Edinburgh,* in 1934 with a complaint of difficulty in swallowing, which was found to be due to achalasia of the cardia. She was treated *by the passage of a mercury bougie, and after leaving the* hospital she continued to pass the bougie herself at about once a fortnight for the next fifteen years, always lubricating the tube well with glycerin. In time the tape attached to the bougie wore off but she did not bother to replace it, always relying on holding the end firmly between her fingers.

At 9 A.M. on the morning of admission, she passed the tube, carefully lubricated, as usual. This time however it slipped, and, having no tape attached to check its passage, down it went. The patient tried to make herself vomit by tickling the back of her throat, but when this proved unsuccessful her doctor (Dr. A. D. F. Corrigall) was called in, and she was sent to the Royal Infirmary.

On admission she was a thin little woman, not unduly alarmed by her experience and not in any particular discomfort.



Bougie in stomach: A, anteroposterior view with patient standing, showing stomach dragged down into pelvis; B, lateral view with patient lying down.

---

[1] Dunlop, D. M., Davidson, L. S. P., McNee, J. W. Textbook of Medical Treatment. Edinburgh, 1939.

X-ray examination (see figure) confirmed her story. Mr. Stewart and I both concluded that the tube was in the stomach, which had been dragged down into the pelvis by the weight of the mercury. The patient began to have abdominal pain and vomited several times in the early afternoon, so it was decided to operate forthwith.

Under general anæsthesia—thiopentone, cyclopropane, and *d*-tubocurarine chloride—a left upper paramedian incision was made. The stomach was found distorted into a J shape, passing down into the pelvis, and the mercury bougie was easily palpable through its wall. A small incision was made in the anterior wall of the stomach at right-angles to the long axis, and the tube was grasped with ring forceps and easily withdrawn. It was 33 in. long and weighed 19 oz. The incision in the stomach was closed in three layers and the abdomen closed without drainage.

The patient made an uninterrupted recovery. She was transferred to a convalescent home on June 27, and when seen on Aug. 23 after five weeks at home was in excellent health. Her chief concern had been that the mercury tube, having been successfully retrieved, might get lost in hospital. She intended to start passing the bougie as soon as she felt the need, but in future she would see that a piece of tape was firmly tied to its end.

I am grateful to Mr. R. Leslie Stewart for permission to record this case.

Preliminary Communication

DIRECT MEDULLARY ARTERIOLES AND ARTERIOVENOUS ANASTOMOSES IN THE ARCUATE SPONGES OF THE KIDNEY

During a hundred years of controversy over the exact anatomy of the renal blood-vessels, attention has been fixed on the results of injections. Few people seem to have looked closely at ordinary microscopical sections of the main site of dispute—the corticomedullary boundary. Examination of serial sections of many human kidneys has convinced us that arteriovenous anastomoses do exist, and that the medulla has an arterial blood-supply *independent of the glomerular circulation*. These anatomical facts have implications in every phase of renal function and pathology.

ANATOMY OF JUXTAMEDULLARY BLOOD-VESSELS

Almost immediately after their entry into the kidney the branches of the renal artery take up a position between the medulla and cortex, and there is no anatomical reason for separating them into interlobar and arcuate arteries. They may conveniently all be called arcuate arteries. Von Möllendorff[1] discusses their course fully. While in this site they branch frequently, so that one sees arcuate arteries of widely varying sizes. Their special feature, and one that has been almost completely neglected, is that they are accompanied by bundles of smooth muscle. These bundles are situated only on one side of the artery and consist of alternate bands of smooth muscle and collagen with varying amounts of elastic fibres. The muscle-fibres all run longitudinally and parallel to the artery, except for a peripheral thin circumferential muscular capsule which encloses the bundle and attaches it to the adventitia of the artery. The muscle bundles run the full length of the arcuate arteries and branch when the arteries branch, but are not usually continued on to the cortical (so-called interlobular) arteries. The peripheral capsule makes the muscle bundles impenetrable by any blood-vessels except at the line of junction between artery and muscle bundle.

When cut in cross-section, most of these bundles are seen to contain one or two arterioles also cut in cross-section and about the calibre of an afferent glomerular artery. These arterioles come directly from the arcuate arteries into the muscle bundle, and their subsequent course is of great interest. They run quite straight for a short distance and then show a remarkable change in the character of their cell structure. The layers become lost, and the wall is composed of loosely attached abundant concentric hyperchromatic plump cells. The arteriole is often tightly coiled at this point, and is always closely invested by a mesh of sinusoids lined by a single layer of cells. These sinusoids form coils and networks inside the muscle bundle and eventually drain into an arm of one of the big veins. Open communications between the sinusoids and the arteriolar coil are extremely difficult to demonstrate, but we have seen a few, and from collateral evidence we believe that the main function of these structures is that of an arteriovenous shunt.

After leaving the coil the arteriole regains its normal structure, runs straight again, and then undergoes the same changes one or more times. It then leaves the muscle bundle at right angles to the muscle-fibres and breaks up into a leash of vessels which supply the peripheral part of the medulla. The whole system of thin-walled sinusoids inside the muscle bundle forms a remarkable sponge-work, the spaces of which are commonly mistaken for lymphatics. We consider that the most suitable name for this system is "the arcuate sponge."

APPEARANCES OF THE ARCUATE SPONGE

The muscle bundles may be seen in all routine sections of the corticomedullary zone. The sponge is commonly empty: and, because its sinusoids have no wall other than endothelium, the only evidence of their existence is the presence of a few elongated small darkly-staining cells which seem out of place in their setting of muscle and collagen fibres.

Another common appearance of the arcuate sponge depends on the frequent presence in its centre of a branch of the renal vein. Like most of the intrarenal veins this tributary achieves increase in volume by a change in its shape. When nearly empty it is a fissure; when full it is circular in cross-section, and then the main body of the muscle bundle caps it on the side opposite to the artery. This appearance led von Möllendorff to describe the muscle bundles as eccentric thickenings of the walls of veins. The sinusoids of the sponge often open into this central vein by a series of tight coils which seem to have a valvular action. There may be a clue here to why the system has not been noticed in most injected specimens.

A rarer appearance of the arcuate sponge, and the only one which allows its nature to be studied, is seen when the sponge spaces are distended with blood. The sinusoids can then be seen to be in free communication with the veins, and sometimes a communication with the arteriole also can be made out. The blood-vessels we have described have been seen and illustrated by Golubew,[2] who discovered them by means of silver-nitrate injections and emphasised the difficulty of demonstrating them by any other methods. We feel that the reason why his work has not been accepted is that he omitted to define the site of these vessels so that they could be recognised in ordinary histological preparations. Their presence inside the muscle bundles of the arcuate arteries makes their identification a matter of no great difficulty.

Medical Societies

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY

Causes of Death in the Aged

AT a meeting of the Devon and Exeter Medico-Chirurgical Society on Dec. 15, Dr. G. STEWART SMITH discussed the fate of people over 65 years of age. At the beginning of the century this group comprised 3% of the population; now the figure was 11%, and by the end of the century it would be 20%. In 1901 there were only 467 per 10,000 of the population; in 1945 there were 1146. If this group was to help to support itself, as it must, we should have to comprehend its special medical and surgical problems.

Dr. Smith reported on 1785 cases, aged 65 or over, which had come to autopsy over a period of 11 years; and he placed 1677 of these in 13 main categories (see accompanying table). All the patients had died in municipal hospitals and most came from the lower-income groups.

CAUSES OF DEATH IN 1677 OUT OF 1785 CASES, AGED OVER 65, EXAMINED POST MORTEM.

Cause of death	Male	Female	Total	Percentage of whole series
Coronary occlusion	58	45	103	5·7
Atherosclerosis and hypertension ..	90	70	160	9·0
Cerebral hæmorrhage and thrombosis	48	44	92	5·0
Chronic bronchitis and bronchiectasis	76	28	104	5·8
Prostatic enlargement	144	—	144	8·0
Acute infections	90	54	144	8·0
"Acute abdomen"	73	86	159	9·0
Gastric and duodenal ulcer	66	27	93	5·2
Chronic nephritis	14	17	31	1·7
Blood diseases	16	18	34	1·9
Trauma	24	24	48	2·7
Tuberculosis	41	12	53	3·0
Cancer	342	170	512	28·5
Totals	1082	595	1677	93·5

The first three categories comprised the degenerative cardiovascular lesions and accounted for one-fifth of all the deaths in this series, compared with two-fifths in the Registrar-General's figures. Dr. Smith held that coronary disease in those over 65 differed in some unexplained way from that in younger subjects. Cerebral hæmorrhage accounted for only 5% of deaths in this series—a figure lower than might have been expected. Chronic bronchitis and bronchiectasis, though present in many cases, could be regarded as the real cause of death in only 6%. Simple prostatic enlargement accounted for 8%, and some of these patients might have survived had they submitted to surgical treatment some years earlier. Among the acute infections (8%), lobar pneumonia and bronchopneumonia and acute septic conditions were the most numerous, but many of these occurred in pre-antibiotic days.

Acute abdominal conditions (excluding those arising from carcinoma or peptic ulcer) accounted for nearly one-tenth of the total deaths—a relatively high proportion, as might have been expected in a purely hospital series. The important causes of the 159 deaths in this group were as follows:

Cause of death	*No. of cases*
Strangulation or volvulus	73
Acute appendicitis	17
.. ..	36
.. ..	14
.. ..	12
Total	152

Strangulated hernia and volvulus, which in many cases might have been treated surgically with success if diagnosed earlier, caused 73 deaths. The complications and sequelæ of peptic ulcer—perforation and peritonitis, and, to a lesser extent, hæmorrhage—caused one-twentieth of the deaths. Here again many of these cases arrived at hospital too late for successful surgical intervention. Chronic nephritis, blood diseases, and trauma were insignificant groups, and tuberculosis (generally of an extensive fibrocaseous type) was responsible, as might be expected in this age-group, for no more than 3% of deaths.

There remained the last and most important single cause of death—malignant neoplasm, which deserved detailed consideration. The Registrar-General's report for the whole country in the decade 1936–1945 gave cancer as the cause of death in one-fifth of all cases in the age-group under consideration. In this autopsy series the figure was higher—one-third of all causes of death. The total was made up as follows:

Site	*No. of cases*	*Site*	*No. of cases*
Lung	119	Breast	16
Stomach	71	Uterus and cervix ..	12
Intestine	71	Kidney	11
Pancreas	36	Larynx and pharynx	11
Prostate	35	Ovary	9
Bladder	30	Sarcoma	9
Rectum	27	Thyroid	1
Gallbladder	18	Other	19
Œsophagus	17		

In this series no less than 119 of the growths were bronchogenic—100 in men and 19 in women. The Registrar-General's report stated that lung cancer had increased continuously and rapidly at every age-period in both sexes and now constituted 30% of all cancers. This must surely be a true increase, and not merely an apparent increase due solely to improved methods of diagnosis. Moreover, lung cancer had a geographical distribution greatest in industrial centres and fading away towards rural areas. No case could be made against tobacco smoke, but the presence of minute quantities of radioactive isotopes in the atmosphere of industrial towns and the use of tar on roads both warranted further investigation. Cancer sites in this series accorded with general experience, but there was a relatively large number of cases of carcinoma of the gall-bladder.

Dr. Smith had been impressed by the relatively large number of deaths due to diseases which, if properly and promptly treated, were often curable, and by the relatively small number of deaths due to purely degenerative, "senile" conditions.

LIVERPOOL MEDICAL INSTITUTION

Cardio-œsophageal Obstruction

AT a meeting on Dec. 15, with Prof. CHARLES WELLS, the president, in the chair, Mr. RONALD EDWARDS read a paper on Cardio-œsophageal Obstruction.

Mr. Edwards described the more common causes of obstruction at the cardio-œsophageal junction—cardiospasm, peptic ulceration and stricture, and malignant disease. The salient feature was dysphagia. This started as a definite pain due to excessive peristalsis, but as soon as the circular-muscle fibres weakened dilatation took place, and pain was replaced by a sensation of distension. With long-standing obstruction the œsophagus might become a functionless sac. Hypersalivation and regurgitation were common, but vomiting of gastric contents was usually impossible. The caloric value of the diet progressively diminished as it became more fluid, and hypoproteinæmia supervened; this might be very difficult to correct and increased the surgical hazard. In cardiospasm, the œsophagus acted as a "drip-feed" and loss of weight might be long delayed; through spending a large part of his life in eating, the unfortunate patient was liable to get into economic and social difficulties.

Peptic ulceration of the œsophagus was due to functional incompetence of the cardiac sphincter associated with widening of the œsophagogastric angle, secondary to hiatus herniation. In a few people there was a wide hiatus, due to late descent of the stomach in embryological life. True congenital short œsophagus was present in only about 5% of cases. Paraœsophageal hernia without shortening of the œsophagus did not produce peptic ulceration. Secondary strictures formed if hyperchlorhydria was present, and associated juxtapyloric ulcers were common.

Carcinoma involving the sphincter was more commonly adenocarcinoma than squamous-cell, and the area 5 mm. each side of the œsophagogastric mucosal junction was very prone to malignant disease. Mr. Edwards described three cases of adenocarcinoma arising in intraœsophageal gastric mucous membrane. In every case the lymph-glands around the cœliac axis were involved early. It was necessary to remove the lesser omentum, greater omentum, cœliac nodes, mediastinal nodes, and suprapancreatic nodes. Adenocarcinoma called for removal of the lower end of the œsophagus, two-thirds of the pancreas, spleen, and related nodes in continuity, and for an œsophagojejunal anastomosis. For a squamous-cell carcinoma a subtotal gastrectomy might be performed, and œsophagogastric anastomosis completed the operation; but it was necessary to perform extensive nodal resection similar to that in the previous operation.

The treatment of cardiospasm, if simple measures failed, was by Heller's operation of œsophagocardiomyotomy, which should be done early, preferably through the abdomen; the incision down to the mucosa must be at least 2 in. long. In 15 cases this procedure had been uniformly successful. Other operations were not recommended.

The treatment of well-established peptic ulceration was difficult; repeated dilatations, alkalis, and sleeping in the erect position would help. If the condition was found early, cure might result from restoring the normal anatomy. Excision of stricture with œsophagogastric anastomosis after two-thirds resection of stomach had been recommended, but the experience was not great enough to evaluate this procedure.

With regard to carcinoma of the stomach, Mr. Edwards made a plea for more radical treatment, in view of the poor long-term results. The postoperative course might be difficult owing to hypoproteinæmia and vitamin deficiency, and before operation care must be taken to make good these deficiencies. Of 21 cases in which œsophagogastric resection had been performed, 2 had died after operation—one from bronchopneumonia three days afterwards, and one from hypoproteinæmia nine weeks afterwards. The patients, 4 of whom were over seventy years of age, tolerated these operations very well. Follow-up showed that of 5 patients operated on at least two years ago, 4 survived. The main mortality was from metastases in the 40–50 age-group; the older age-groups did well.

Reviews of Books

Darmbrand: Enteritis Necroticans

K. HANSEN and others from the Städtische Krankenanstaten of Lubeck. Stuttgart: Thieme. 1949. Pp. 212. D.M. 25.

FROM their study of cases seen in Germany in 1946 and 1947 the authors of this monograph bring forward evidence that *Darmbrand* is a distinct and recognisable disorder, of epidemic type, not previously separated from other diseases. These cases occurred for the most part in the North German coastal areas in explosive outbreaks in the summer and autumn months of 1946–47. The condition may affect any part of the intestinal tract, and its essential characteristic is a coloured necrosis resembling that of burnt tissue. This necrosis may lead to death from early perforation, to stenosis with perhaps subsequent perforation, and of course to ulceration and bleeding in the acute stage. Of 364 cases recorded 22% were fatal, most of the deaths being in people over fifty years of age. The disease was commonest in August and September, and was noted especially in Lübeck, Hamburg, and Kiel. The authors describe their cases with careful detail and record the pathology, the diagnosis and complications, and in several cases the results of surgical treatment by gut resection. Their monograph, which is illustrated by numerous X-ray photographs and some coloured illustrations, deserves study by those interested in gastro-enterology. A satisfactory English version of the German title has not yet been suggested. German cases were described in our columns last spring (1949, i, 519) under the name of necrotic jejunitis.

Visual Development

Vol. I. J. H. PRINCE, F.R.M.S. Edinburgh: E & S. Livingstone. Pp. 418. 50*s*.

Mr. Prince's book, apart from discursive accounts of the anatomy and physiology of the visual apparatus properly speaking, is packed with items of curious information about many matters indirectly related to vision; and its entertainment value is enhanced by an abundance of photographic and coloured illustrations. As Prof. Hamilton Hartridge points out in an introduction, it is full of information and raises many problems of the greatest interest which call for solution. But it is uneven in its treatment of the many subjects with which it deals, and here and there occur rather startling statements which arrest the reader's attention somewhat abruptly (as, for instance, the remark that "primitive man's remains have been found in conditions which suggest that he may have been well advanced as much as eighteen million years ago"). The lack of adequate references makes it difficult to distinguish the author's own observations from those he quotes from the work of others. He says in the preface that volume II (in preparation) will be concerned with "attempts at proving points and presenting new theories."

Die Psychohygiene

Editor: Dr. MARIA PFISTER-AMMENDE, Zürich. Berne: Huber. 1949. Pp. 423. Sw. fr. 28.

MENTAL hygiene on a world-wide scale has lately been propagated as a panacea against many troubles of our times. Its theoretical aims are rather vague, but practical mental welfare work can claim results in many fields. This is the impression one gains from this Swiss publication in which over 40 writers do homage to Dr. H. Meng, of Basle, holder of the only professorial chair of mental hygiene in Europe, on the occasion of his 60th birthday. Contributions from Switzerland reflect the high standard of mental health services and of psychiatric personalities outside and inside hospitals. By far the most interesting articles deal with welfare work among the 300,000 refugees from all parts of Europe, prisoners-of-war, displaced persons, and deprived children received by the Swiss authorities since April, 1940. Organisation, selection and training of welfare workers, and special difficulties with certain national groups and their psychological problems are described in some detail; but this must be only a fraction of the large and unique Swiss experience in practical mental hygiene, from which other peoples could greatly profit.

That mental hygiene as a movement and practice has not made the same progress in many countries is obvious enough from the reports in this book from Britain, the United States, France, Hungary, Denmark, and Berlin—in spite of some rosy articles suited to the festive occasion for which it was compiled. It is not a comprehensive picture, for some of the best-known work in the field of social and preventive psychiatry—that of the Children's Police in Holland, and the mental-aftercare organisations in Amsterdam and New York State, and preventive work directed against crime and other forms of asocial behaviour in the Scandinavian countries—has not been included. It is difficult to gather from the book a clear idea of Dr. Meng's own teaching on the

Medical Societies

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY

Causes of Death in the Aged

AT a meeting of the Devon and Exeter Medico-Chirurgical Society on Dec. 15, Dr. G. STEWART SMITH discussed the fate of people over 65 years of age. At the beginning of the century this group comprised 3% of the population: now the figure was 11%, and by the end of the century it would be 20%. In 1901 there were only 467 per 10,000 of the population; in 1945 there were 1146. If this group was to help to support itself, as it must, we should have to comprehend its special medical and surgical problems.

Dr. Smith reported on 1785 cases, aged 65 or over, which had come to autopsy over a period of 11 years; and he placed 1677 of these in 13 main categories (see accompanying table). All the patients had died in municipal hospitals and most came from the lower-income groups.

CAUSES OF DEATH IN 1677 OUT OF 1785 CASES, AGED OVER 65, EXAMINED POST MORTEM.

Cause of death	Male	Female	Total	Percentage of whole series
Coronary occlusion	58	45	103	5·7
Atherosclerosis and hypertension ..	90	70	160	9·0
Cerebral hæmorrhage and thrombosis	48	41	92	5·0
Chronic bronchitis and bronchiectasis	76	26	104	5·8
Prostatic enlargement	141	—	141	8·0
Acute infections	90	54	144	8·0
"Acute abdomen"	73	86	159	9·0
Gastric and duodenal ulcer	66	27	93	5·2
Chronic nephritis	14	17	31	1·7
Blood diseases	16	18	34	1·9
Trauma	24	24	48	2·7
Tuberculosis	41	12	53	3·0
Cancer	342	170	512	28·5
Totals	1082	595	1677	93·5

The first three categories comprised the degenerative cardiovascular lesions and accounted for one-fifth of all the deaths in this series, compared with two-fifths in the Registrar-General's figures. Dr. Smith held that coronary disease in those over 65 differed in some unexplained way from that in younger subjects. Cerebral hæmorrhage accounted for only 5% of deaths in this series—a figure lower than might have been expected. Chronic bronchitis and bronchiectasis, though present in many cases, could be regarded as the real cause of death in only 6%. Simple prostatic enlargement accounted for 8%, and some of these patients might have survived had they submitted to surgical treatment some years earlier. Among the acute infections (8%), lobar pneumonia and bronchopneumonia and acute septic conditions were the most numerous, but many of these occurred in pre-antibiotic days.

Acute abdominal conditions (excluding those arising from carcinoma or peptic ulcer) accounted for nearly one-tenth of the total deaths—a relatively high proportion, as might have been expected in a purely hospital series. The important causes of the 159 deaths in this group were as follows:

Cause of death	*No. of cases*
[illegible] or volvulus	73
[illegible]	17
[illegible]	36
[illegible]	14
[illegible]	12
Total	152

Strangulated hernia and volvulus, which in many cases might have been treated surgically with success if diagnosed earlier, caused 73 deaths. The complications and sequelæ of peptic ulcer—perforation and peritonitis, and, to a lesser extent, hæmorrhage—caused one-twentieth of the deaths. Here again many of these cases arrived at hospital too late for successful surgical intervention. Chronic nephritis, blood diseases, and trauma were insignificant groups, and tuberculosis (generally of an extensive fibrocaseous type) was responsible, as might be expected in this age-group, for no more than 3% of deaths.

There remained the last and most important single cause of death—malignant neoplasm, which deserved detailed consideration. The Registrar-General's report for the whole country in the decade 1936–1945 gave cancer as the cause of death in one-fifth of all cases in the age-group under consideration. In this autopsy series the figure was higher—one-third of all causes of death. The total was made up as follows:

Site	*No. of cases*	*Site*	*No. of cases*
Lung	119	Breast	16
Stomach	71	Uterus and cervix ..	12
Intestine	71	Kidney	11
Pancreas	36	Larynx and pharynx	11
Prostate	35	Ovary	9
Bladder	30	Sarcoma	9
Rectum	27	Thyroid	1
Gallbladder	18	Other	19
Œsophagus	17		

In this series no less than 119 of the growths were bronchogenic—100 in men and 19 in women. The Registrar-General's report stated that lung cancer had increased continuously and rapidly at every age-period in both sexes and now constituted 30% of all cancers. This must surely be a true increase, and not merely an apparent increase due solely to improved methods of diagnosis. Moreover, lung cancer had a geographical distribution greatest in industrial centres and fading away towards rural areas. No case could be made against tobacco smoke, but the presence of minute quantities of radioactive isotopes in the atmosphere of industrial towns and the use of tar on roads both warranted further investigation. Cancer sites in this series accorded with general experience, but there was a relatively large number of cases of carcinoma of the gall-bladder.

Dr. Smith had been impressed by the relatively large number of deaths due to diseases which, if properly and promptly treated, were often curable, and by the relatively small number of deaths due to purely degenerative, "senile" conditions.

LIVERPOOL MEDICAL INSTITUTION

Cardio-œsophageal Obstruction

AT a meeting on Dec. 15, with Prof. CHARLES WELLS, the president, in the chair, Mr. RONALD EDWARDS read a paper on Cardio-œsophageal Obstruction.

Mr. Edwards described the more common causes of obstruction at the cardio-œsophageal junction—cardiospasm, peptic ulceration and stricture, and malignant disease. The salient feature was dysphagia. This started as a definite pain due to excessive peristalsis, but as soon as the circular-muscle fibres weakened dilatation took place, and pain was replaced by a sensation of distension. With long-standing obstruction the œsophagus might become a functionless sac. Hypersalivation and regurgitation were common, but vomiting of gastric contents was usually impossible. The calorie value of the diet progressively diminished as it became more fluid, and hypoproteinæmia supervened; this might be very difficult to correct and increased the surgical hazard. In cardiospasm, the œsophagus acted as a "drip-feed" and loss of weight might be long delayed; through spending a large part of his life in eating, the unfortunate patient was liable to get into economic and social difficulties.

Peptic ulceration of the œsophagus was due to functional incompetence of the cardiac sphincter associated with widening of the œsophagogastric angle, secondary to hiatus herniation. In a few people there was a wide hiatus, due to late descent of the stomach in embryological life. True congenital short œsophagus was present in only about 5% of cases. Paraœsophageal hernia without shortening of the œsophagus did not produce peptic ulceration. Secondary strictures formed if hyperchlorhydria was present, and associated juxtapyloric ulcers were common.

Carcinoma involving the sphincter was more commonly adenocarcinoma than squamous-cell, and the area 5 mm. each side of the œsophagogastric mucosal junction was very prone to malignant disease. Mr. Edwards described three cases of adenocarcinoma arising in intraœsophageal gastric mucous membrane. In every case the lymph-glands around the cœliac axis were involved early. It was necessary to remove the lesser omentum, greater omentum, cœliac nodes, mediastinal nodes, and suprapancreatic nodes. Adenocarcinoma called for removal of the lower end of the œsophagus, two-thirds of the pancreas, spleen, and related nodes in continuity, and for an œsophagojejunal anastomosis. For a squamous-cell carcinoma a subtotal gastrectomy might be performed, and œsophagogastric anastomosis completed the operation; but it was necessary to perform extensive nodal resection similar to that in the previous operation.

The treatment of cardiospasm, if simple measures failed, was by Heller's operation of œsophagocardiomyotomy, which should be done early, preferably through the abdomen: the incision down to the mucosa must be at least 2 in. long. In 15 cases this procedure had been uniformly successful. Other operations were not recommended.

The treatment of well-established peptic ulceration was difficult; repeated dilatations, alkalis, and sleeping in the erect position would help. If the condition was found early, cure might result from restoring the normal anatomy. Excision of stricture with œsophagogastric anastomosis after two-thirds resection of stomach had been recommended, but the experience was not great enough to evaluate this procedure.

With regard to carcinoma of the stomach, Mr. Edwards made a plea for more radical treatment, in view of the poor long-term results. The postoperative course might be difficult owing to hypoproteinæmia and vitamin deficiency, and before operation care must be taken to make good these deficiencies. Of 21 cases in which œsophagogastric resection had been performed, 2 had died after operation—one from bronchopneumonia three days afterwards, and one from hypoproteinæmia nine weeks afterwards. Darmbrand: Enteritis Necroticans

K. Hansen and others from the Städtische Krankenanstaten of Lübeck. Stuttgart: Thieme. 1949. Pp. 212. D.M. 25.

From their study of cases seen in Germany in 1946 and 1947 the authors of this monograph bring forward evidence that *Darmbrand* is a distinct and recognisable disorder, of epidemic type, not previously separated from other diseases. These cases occurred for the most part in the North German coastal areas in explosive outbreaks in the summer and autumn months of 1946–47. The condition may affect any part of the intestinal tract, and its essential characteristic is a coloured necrosis resembling that of burnt tissue. This necrosis may lead to death from early perforation, to stenosis with perhaps subsequent perforation, and of course to ulceration and bleeding in the acute stage. Of 364 cases recorded 22% were fatal, most of the deaths being in people over fifty years of age. The disease was commonest in August and September, and was noted especially in Lübeck, Hamburg, and Kiel. The authors describe their cases with careful detail and record the pathology, the diagnosis and complications, and in several cases the results of surgical treatment by gut resection. Their monograph, which is illustrated by numerous X-ray photographs and some coloured illustrations, deserves study by those interested in gastroenterology. A satisfactory English version of the German title has not yet been suggested. German cases were described in our columns last spring (1949, i, 519) under the name of necrotic jejunitis.

Visual Development

Vol. I. J. H. Prince, F.R.M.S. Edinburgh: E & S. Livingstone. Pp. 418. 50s.

Mr. Prince's book, apart from discursive accounts of the anatomy and physiology of the visual apparatus properly speaking, is packed with items of curious information about many matters indirectly related to vision; and its entertainment value is enhanced by an abundance of photographic and coloured illustrations. As Prof. Hamilton Hartridge points out in an introduction, it is full of information and raises many problems of the greatest interest which call for solution. But it is uneven in its treatment of the many subjects with which it deals, and here and there occur rather startling statements which arrest the reader's attention somewhat abruptly (as, for instance, the remark that "primitive man's remains have been found in conditions which suggest that he may have been well advanced as much as eighteen million years ago"). The lack of adequate references makes it difficult to distinguish the author's own observations from those he quotes from the work of others. He says in the preface that volume II (in preparation) will be concerned with "attempts at proving points and presenting new theories."

Die Psychohygiene

Editor: Dr. Maria Pfister-Ammende, Zürich. Berne: Huber. 1949. Pp. 423. Sw. fr. 28.

Mental hygiene on a world-wide scale has lately been propagated as a panacea against many troubles of our times. Its theoretical aims are rather vague, but practical mental welfare work can claim results in many fields. This is the impression one gains from this Swiss publication in which over 40 writers do homage to Dr. H. Meng, of Basle, holder of the only professorial chair of mental hygiene in Europe, on the occasion of his 60th birthday. Contributions from Switzerland reflect the high standard of mental health services and of psychiatric personalities outside and inside hospitals. By far the most interesting articles deal with welfare work among the 300,000 refugees from all parts of Europe, prisoners-of-war, displaced persons, and deprived children received by the Swiss authorities since April, 1940. Organisation, selection and training of welfare workers, and special difficulties with certain national groups and their psychological problems are described in some detail; but this must be only a fraction of the large and unique Swiss experience in practical mental hygiene, from which other peoples could greatly profit.

That mental hygiene as a movement and practice has not made the same progress in many countries is obvious enough from the reports in this book from Britain, the United States, France, Hungary, Denmark, and Berlin—in spite of some rosy articles suited to the festive occasion for which it was compiled. It is not a comprehensive picture, for some of the best-known work in the field of social and preventive psychiatry—that of the Children's Police in Holland, and the mental-aftercare organisations in Amsterdam and New York State, and preventive work directed against crime and other forms of asocial behaviour in the Scandinavian countries—has not been included. It is difficult to gather from the book a clear idea of Dr. Meng's own teaching on the principles of mental hygiene; he evidently lays emphasis on the collaboration of educational psychologist, social scientist, and psychiatrist, on the importance to the community of borderline cases of mental abnormality, and on the prevention where possible of the more severe forms of mental illness by the use of psycho-analytic principles—all too familiar ground to readers in English-speaking countries. After perusing the 400 beautifully printed pages they will turn again reflectively to the quotation from Goethe's Wilhelm Meister in the preface: "If one once knows all the essentials, one ceases to be talkative."

Streptomycin and Dihydrostreptomycin in Tuberculosis

Reports of research including studies sponsored by the American Trudeau Society (Medical Section, National Tuberculosis Association). Editors: H. McLeod Riggins, M.D.; H. Corwin Hinshaw, M.D. New York: National Tuberculosis Association. 1949. Pp. 554. $7.50.

This volume is of historic interest, for it gathers together the most important papers on streptomycin published in the United States since the first account of its discovery by Schatz and Waksman in 1944. The early experimental and clinical studies by Feldman and Hinshaw, the clinical reports by McDermott and his co-workers, the 1948 report of the Veterans Administration Streptomycin Committee, and the first reports on dihydrostreptomycin, are all reprinted here. Special articles on the bacteriological problems have been written for this volume by Steenken and Youmans, on the pathology by Baggenstoss and Medlar, and on toxicity by Fowler and others.

In the Trudeau Society investigations, which form the nucleus of the book, a main finding was that large daily doses (1·5–3·0 g.) gave better therapeutic results than smaller doses; but the treatment groups differed so much from one another at the outset, and so many results appear as "not stated," that the findings must be hedged with reservations, and cannot be held to invalidate the opposite findings by the Veterans Administration. At the same time, clinical reports by the individual investigators offer much enlightened comment on the problems of streptomycin therapy.

The book is handsomely produced, and is a valuable addition to the literature on the chemotherapy of tuberculosis.

The Infancy of Speech and the Speech of Infancy

Leopold Stein, M.D., F.R.A.I., physician in charge of speech therapy, Tavistock Clinic. London: Methuen. 1949. Pp. 209. 21*s*.

Study of the origin and early evolution of language is fundamental for the study of the evolutionary development of the human family; but it is difficult of approach. Dr. Stein's book on the evolution of speech is best regarded as a speculative essay, for (as the prospective reader is informed on the cover) "where direct evidence is lacking he has resorted boldly to analogy and fantasy." The fact is that we have no direct evidence of the linguistic capacity of palæolithic man, and the question naturally arises how far the author is justified in the use which he makes of analogies and fantasies. This is a matter, perhaps, for the individual reader to decide for himself, and in any case Dr. Stein may be commended for his strenuous effort to align all the indirect evidence —provided by comparative philology, by the study of the development of speech in the modern human infant, and by broad psychological principles—with what is known of the evolution of man and of human culture. To those unfamiliar with the notations used for expressing elementary voice sounds, the book is by no means easy to read. At the first mention of lists of phonetic symbols the reader is referred to the index, but unfortunately finds nothing there to help him. Much of the book is a popular account of the development of man and his culture in palæolithic times, and this draws largely on previous popular accounts (rather than specialist studies) for its factual data. Opinions are thus attributed to certain authors which they have really quoted from others. There are not a few inaccuracies of prehistory which are bound to affect the value of the book as a whole. Nevertheless, Dr. Stein's essay has been well worth while, for he demonstrates quite candidly the limitations of the sort of evidence on which he is bound to rely, and at the same time indicates the utmost limit to which it is possible to go, on the evidence at present available, in any attempt to elucidate the origin of language.

A Textbook of Bacteriology (6th ed. London: Heinemann. 1949. Pp. 484. 20*s*.).—In this edition of Dr. R. W. Fairbrother's book the sections on milk, the viruses, and the Rh factor have been revised, but otherwise there is little change. Subjects which have only technical interest are wisely omitted, but space is given to the relation of bacteriology to clinical medicine. The book covers the course in reasonable space, but it could be made shorter and better, though medical students, for whom it was written, seem to like it. It has a few useful illustrations but no references.

Proceedings of the Ninth International Congress on Industrial Medicine, London, 1948 (Bristol: John Wright & Sons. 1949. Pp. 1090. 60*s*.).—Those who attended the industrial medicine congress last year will be glad to have this stout memento of an interesting occasion. The book, however, is more than this, for many of the papers reproduced here will be valuable references for many years to come. Photographs, drawings, and diagrams shown at the sessions are well reproduced, and English synopses of foreign papers are provided.

The Filterable Viruses (Supplement no. 2, Bergey's Manual of Determinative Bacteriology. 6th ed. London: Baillière, Tindall, and Cox. 1948. Pp. 172. 20*s*.).—This supplement, by Francis O. Holmes, which was included in the last edition of "Bergey," classifies and names the viruses which cause disease in man, animals, plants, and bacteria, and gives valuable references and information about most of them. We shall miss the pleasant descriptive names of some of the plant viruses—those causing wilts, crinkles, and curls—and it is small consolation to know that mumps and herpes simplex viruses take the latinised names of a pettifogger and a rascal. Children with measles and chickenpox may share the taxonomist's fun when they learn that the generic name of both viruses is Briareus, the hundred-armed giant.

Law Relating to Hospitals (2nd ed. London: H. K. Lewis. 1949. Pp. 587. £2 2*s*.).—The start of the National Health Service has obliged Mr. S. R. Speller, LL.B., to rewrite much of his useful book and to put in a good deal of new matter, not only about the National Health Service Act itself but about the Penicillin Act, 1947, and the Radioactive Substances Act, 1948. Moreover he has taken the bold and helpful course of putting in a chapter on the mental hospitals. Doctors will again find that part II and part III contain much to interest them, and nurses will find their position and obligations defined in part IV. Part V deals entirely with the operation of the Act. As a barrister, as former editor of *The Hospital*, and as secretary of the Institute of Hospital Administrators, Mr. Speller is in a good position to know his subject both in theory and practice, and his survey should be of great use to our profession.

What is Man? (London: C. A. Watt. 1949. Pp. 204. 10*s*. 6*d*.).—The concept of man as a being who carries his evolutionary past as a fixed if inconvenient corollary of his present belongs more to the last than to the present century. It is this approach which may limit the value of Mr. Alfred Machin's essays—or rather aphorisms—for modern biological or sociological readers. He traces the very broad outlines of the conflicts between evolutionary survivals, in the form of instinct and conduct-pattern, and human aspirations; but he adds very little to the pattern of evolutionary rationalism which was far more comprehensively and accurately stated by T. H. Huxley nearly a century ago. It is hard, for example, for a 20th-century reader to come to terms with an author for whom "men hate work . . . (and) have no social instinct," or for whom "sex is one of the aberrant instincts of mankind" because it fails to coincide with civilised institutions. It is difficult to imagine that such a sequence of dogmatic inaccuracies could have been written by anyone familiar with the work of Mead or Unwin on sexual and social patterns, or of any of the more recent workers on the social behaviour of animals. The book is an interesting statement of an obsolete position—more cannot be claimed for it.

THE LANCET

LONDON: SATURDAY, JAN. 7, 1950

Mechanism and Purpose

THE other day an experienced physician was asked what criteria he would apply in judging the efficiency of a hospital: what relative importance would he attach to the qualifications of the staff, the ratio of beds to nurses, the adequacy of special departments, the catering, the facilities for reablement, and the various other items on which inspecting authorities commonly make notes? He replied: "I should not inquire into any of these things. I should simply go into the wards, select six patients, and find out precisely what had been done for them, and the care they had received, since the day of their admission." This wise answer has implications beyond even the hospital services, for it embodies the truth that any kind of machinery, however ingenious, is but a means to an end. In constructing a new mechanical system such as the National Health Service it is probably inevitable that we should at first be preoccupied with its design and control and with the affairs of those who have to work it. But there is a real danger of our eyes becoming fixed on the mechanism rather than on its purpose—which is to benefit all the people of this country, in the home, at work, and in the ward.

There is a particular risk that in focusing closely on the more elaborate parts of the machinery, which certainly need constant attention, some other parts will be neglected. Of course the basic principle of the National Health Service, on which the rest is founded, is that the patient is entitled to *any* kind of medical care he needs at any time. But in fact, as we all know too well, the resources of the service —in money, skill, and labour—are strictly limited; and it is at present quite impossible to provide everybody with comprehensive medical care of the best sort. This means that the way in which the resources are apportioned may make a great difference to the benefit the public actually obtains. The main value of the National Health Service Act is that it permits us, for the first time, to plan medical services as a whole; and this value will be lost if we go on putting all our efforts into making the old wheels turn more smoothly. The time has come to consider how far the system is economical: how far does it give the nation the best possible return for its money?

In terms of expenditure, the cheapest form of medicine is preventive medicine; the next cheapest is efficient care of patients in their homes; and the most expensive is hospital treatment. Anyone concerned with economy must therefore be disturbed by the bias of the National Health Service, in its initial phase, towards the development and improvement of hospital care, at the expense, to some extent, of the communal services and of general practice. The most powerful and best-endowed administrative bodies in the service are the regional hospital boards and the boards of governors, which control almost all the specialist talent. Properly intent on their own enormous tasks, these boards can hardly be expected to give much thought to the needs of other branches of the service; which makes it regrettable, as Dr. FRASER BROCKINGTON[1] has pointed out, that no authority in the regions is in a position to survey the situation objectively and decide whether some of the specialists would be not more usefully employed on preventive or domiciliary work. The decline of the so-called priority dental service for children and expectant and nursing mothers is, we fear, symptomatic of a general, if unintentional, shift of emphasis from preventive to curative work. As Dr. J. L. BURN[2] says, "it is deplorable that the dental resources, so limited in man-power, should be diverted from the needs of the future"; and he may well be right in going on to claim that a tenth of the increase in money for hospital services would, if diverted to public-health services, secure a vast improvement in public health within a generation. While approving the change that has relieved medical officers of health of their responsibility for hospitals, we view with disquiet the signs of a relative decline in their status. Similarly the lack of any sufficient endeavour to restore and rehabilitate general practice gives cause for anxiety even greater than we expressed last New Year. Admittedly general practice in this country was deteriorating long before the National Health Service was introduced, and its further deterioration is due rather to a heavier load than to any legislative alterations made by the Act. But on balance the effects of the Act on such practice have so far been for the worse, and there is little evidence that its problems are being squarely faced. Of the two possible policies, the first is to say that general practice is so often unsatisfactory that the correct course is to compensate for its defects—to develop hospital and specialist services in such a way that the shortcomings of general practitioners become relatively unimportant. This, we cannot help thinking, is the policy that is, consciously or unconsciously, being pursued. Yet if we are right in believing that, at any rate nowadays, patients should never unnecessarily occupy expensive hospital beds, it is definitely the wrong policy. The alternative—the only alternative— is to make a big positive effort to raise the level and prestige of general practice. This can still be done; and we hopefully welcome last week's news that Scotland, again taking a lead, is to make an initial inquiry into the relations between the general practitioner and the hospital and specialist services.

Depressing features in the medical scene as this year opens should not obscure the fact that policies can be changed and mistakes corrected. There is no reason, apart from human fallibility, why the new service, so brilliantly conceived in outline, should not be steadily improved, so that it brings more real benefit to the people—in the home, at work, and in the ward. But this improvement will not come automatically; and, now that the machinery is working, it is becoming urgently necessary to consider whether, or how far, the purpose of the system is being fulfilled to the best of our ability. The review that is needed might well be undertaken by the

2. Annual Report for 1948 by the Medical Officer of Health for the City of Salford.

Central Health Services Council, which was intended to play a really important part as the accessory brain and the voice of the service. Somehow or by someone, the large view must be taken, and we must all be made to feel (as we should) that, amid unavoidable confusion and disappointment and hardship, we are progressing towards a service of high quality, soundly balanced. In the words of Prof. I. G. DAVIES[3]:

> "Looking back on 1948 and the year subsequent, there is discernible a vast national system of medico-social services administered by a number of different types of authority and run by different kinds of administrative machinery. Not even the kindliest critic of this machine could say that it worked smoothly or that its components were properly synchronised with each other. . . . Is it too much to hope that some method will be devised of integrating these different parts into one of the finest national medico-social services yet seen? The parts are all there—it would be a pity to leave them as they are."

Risks of Anti-histamine Medication

THE introduction and development of anti-histamine drugs in the last dozen years has been a notable advance in therapeutics, and their success in allergic diseases has naturally led to their trial in ailments on or beyond the borders of the allergic group. Since they have been particularly valuable in paroxysmal rhinorrhœa, it was inevitable that they should be tried in the common cold. In medicine, we are told, sensible experimentation is preferable to speculation, so such trials were obviously desirable. The ætiologies of the two conditions are generally agreed to be quite different—the one allergic and the other a virus infection—but it was argued that the symptoms of the early coryzal and congestive phases of a cold might be allergic in origin and that at this stage an anti-histamine drug might abort the cold before secondary infection had occurred.[4] Individual practitioners who have experimented on themselves seem to agree that the anti-histamines afford some symptomatic relief, and BREWSTER's[5] trial in the U.S. Navy was encouraging so far as it went, though the plan was subject to serious criticism.[6] On the other hand, PATON, FULTON, and ANDREWES,[7] who emphasised the difficulty of assessing "cold cures," reported a small but carefully controlled experiment to test the value of 'Anthisan' and concluded that the results did not show any dramatic effect of this drug on the common cold. They added this rider concerning their findings:

> "We do not bring them forward as evidence that there is no beneficial action, but only to draw attention to the necessity for rigorous control of any test of a remedy for colds; the need to depend on subjective judgments by patient and clinician alike make such tests particularly difficult."

A cautious attitude on the part of doctors is highly desirable, if only because the Poisons Board has not, so far, taken steps to prevent the public from buying these toxic drugs over the counter. It is said that by the Monday evening after an article had appeared in a Sunday newspaper on the virtues of anti-histamines as a cold cure, stocks of them in the chemists' shops were almost exhausted. It seems likely that of the thousands of people who bought these drugs at least a third would experience some toxic effect, such as drowsiness, giddiness, or the peculiar psychological states of unreality and disorientation. Trivial as this may appear, there will certainly be tragic consequences if drivers of cars and public transport dose themselves indiscriminately with anti-histamines. The decision not to include these drugs in the Poisons Schedules was doubtless made at a time when it could reasonably be assumed that the people taking them would normally be under immediate medical supervision. Today this applies only to a minority, and the change of circumstances has created a potential danger which merits immediate intervention by the Ministry of Health. The possibility that a labyrinthitis may develop on withdrawal of anti-histamine therapy, of which three examples are reported by CHERRY[8] for South Australia, also deserves consideration.

According to reports reaching this office several children have died from eating sugar-coated anti-histamine tablets as sweets. In cases of acute poisoning by anti-histamines the obvious antidote is histamine acid phosphate, injected subcutaneously in doses of 0·1 mg. per kg. of body-weight. Tablets which are vividly coloured and sweet to taste can scarcely be resisted by a normal child, and we have the unfortunate experience with ferrous sulphate tablets as evidence of this fact. Responsibility for safe disposal of poisons in the household rests with its adult members; but manufacturers might consider whether the time has not come to incorporate into the coating of these tablets a trace of some bitter substance which would discourage a child without causing undue hardship to adults.

Prognosis in Myocardial Infarction

THE mortality from coronary disease appears to be increasing. In his Harveian oration of 1946, CASSIDY[9] voiced his conviction that the increase could not be explained by more accurate certification; and he pointed out that relatively few cases were seen by the great physicians of the past, such as MACKENZIE and OSLER, or by the astute morbid anatomists of those days, though they were fully alive to the existence of the condition. According to the Registrar-General's returns, deaths in England and Wales from coronary disease numbered 1880 in 1926, 25,012 in 1945, and 33,168 in 1947. This is a startling increase; and RYLE and RUSSELL,[10] after allowing for changing fashions in diagnosis, amendments to the international classification of causes of death, and the lengthening span of life, conclude that the increase is real. Similar figures have in fact been published in the U.S.A., where 28,286 fatal cases were recorded in 1930, 101,467 in 1940, and 113,636 in 1942.[11] And at the Royal Adelaide Hospital,[12] in Australia, the proportion of necropsies showing cardiac infarction rose from 1·1% in 1935 to 4·5% in 1946

In myocardial infarction death often follows immediately on the onset of symptoms, or it may come without any warning at all; probably some 30% of all natural sudden deaths are due to coronary-

artery disease.[13] Statistics on prognosis are unsatisfactory for several reasons. There are inevitable variations between cases admitted to hospital and those treated at home. Some patients will be regarded as too ill to be moved to hospital, or will refuse to go: others will be regarded as too ill to be nursed at home, or circumstances may make home nursing impossible. On the whole, however, the more serious cases will be treated in hospital, and it is on hospital groups that most reports are made. On the other hand, hospital treatment may well be more effective, especially in these days of anticoagulants. Some years ago PARKINSON and BEDFORD[14] reported that of 100 patients who did not die immediately, 23 died within six months and a further 7 within two years. CONNER and HOLT[15] found shortly afterwards that of 209 cases about 16% died in the first attack; of those who survived this, 75% were alive at the end of a year, 56% at the end of two years, 21% at the end of five years, and 3·5% at the end of ten years. In 1931 WHITE and BLAND[16] recorded that 10% died within a month and a further 17% within a year. In 1935 BEDFORD[17] remarked that the outlook is always uncertain until the danger period of the first three weeks is past, though the chances are definitely in favour of recovery; that 25% of cases died within 6–8 weeks: and that thereafter there was a good chance of fair health and activity for some years, and a possibility of surviving more than five years. PALMER[18] found that of those who survived the first three months 75% were alive after five years and almost 40% after ten years. LEVINE and ROSENBAUM,[19] however, observed that the average expectation of life was only 3½ years. In a recent investigation of 866 cases in Servicemen under 40 years of age, YATER and his colleagues[20] found that of 450 who died no less than 83% did so within twenty-four hours of the onset of symptoms. How grave myocardial infarction can be in a hospital series has lately been illustrated by KATZ and his colleagues[21] of the Michael Reese Hospital, Chicago, who analysed 488 cases admitted to a general hospital. About a quarter of these patients died in the first two months, about half had died by the end of a year, about two-thirds by the end of the third year, and about four-fifths by the end of five years. Thus the survival-rate fell from 72% at two months to 55% at a year and to 16% at five years.

It is now realised not only that infarction may be painless but that coronary occlusion often takes place without infarction and infarction without occlusion.[22,23] It is generally conceded, too, that the prognosis for patients with angina pectoris is better than for those with clinically manifest infarction. Among 3000 cases of angina which were followed up by PARKER and others,[24] the average five-year survival-rate was 71% for women and 58% for men, and the average ten-year survival-rate was 40% for women and 33% for men. Questioning of patients with angina often elicits the history of an episode suggesting myocardial infarction some time—perhaps years—previously: and electrocardiography commonly brings to light unequivocal evidence of previous infarction. Some of these patients have kept on with their work, or gone back to it in a few days, after what in retrospect was clearly an infarction: but others seek advice for even minor pain and have thus been put to bed at home or admitted to hospital. There can be all grades of infarction, from the death of a small area of myocardium, or even of a few fibres, to extensive necrosis of large areas of ventricular wall. Suitable treatment may make all the difference to the outcome. Rest and relaxation are of paramount importance. Some patients will need oxygen and others treatment for shock. Continued pain demands relief, and though morphine is the usual standby GIBSON[25] emphasises the value of aspirin. If a serious arrhythmia develops, quinidine may be life-saving, or it may be useful prophylactically. Digitalis will be needed for congestive failure. Above all, perhaps, there are the possibilities of anticoagulant therapy.

The causes of death in the first two months are worth considering in detail. In KATZ's[21] series, further myocardial infarction was responsible for 65% of the deaths and in that of LEVINE and ROSENBAUM[19] for 40%. Next in importance is pulmonary infarction, and then peripheral arterial embolism, which may involve vital areas such as the brain or mesentery. In an analysis of 1605 clinical cases of myocardial infarction collected from eleven reports, HELLERSTEIN and MARTIN[26] found that 11·5% had clinically detectable lesions due to thrombosis or embolism. In their own series of 160 necropsies, infarction was found in 45%: in 12% of these cases this was held to be the main cause of death and in a further 15% a contributory cause. Here then is a promising field for anticoagulant therapy. Heparin and dicoumarol might well be expected to lower the incidence of mural thrombosis over the site of infarction in the ventricles and hence of arterial embolism. They help to prevent peripheral venous thrombosis, with its risk of subsequent pulmonary infarction: they probably limit the "build-up" of further thrombus behind the obstructed coronary artery: and they may also reduce the likelihood of further coronary thrombosis in other vessels during the period of hospital treatment. The American Heart Association set up a committee in 1946 to collect data on this subject from teaching centres, and the resulting series of 800 cases was divided into two groups. One group was treated in a standard way with dicoumarol, sometimes plus heparin, and the other served as controls. A preliminary report[27] showed encouraging results, which have been confirmed by other workers. Over the six weeks' period of observation, the death-rate in the treated group was 14·9%, compared with 24% in the untreated group. The incidence of thrombo-embolic complications was 11% compared with 25%. Moreover, about half the treated series experienced complications before the anticoagulant drugs had had

time to become fully effective. Since the risk of these complications is greatest in the first four weeks and thereafter decreases rapidly, the prospects for such treatment influencing prognosis are bright. This form of treatment cannot be undertaken in the patient's home and is possible only in a hospital with sufficient laboratory resources. The necessary estimations of prothrombin-time with a daily control require particular care and involve dangers for the unwary. This raises the question whether myocardial infarction should not be regarded as an indication for urgent admission to hospital. With prompt hospital treatment (not to mention inclusion of the many more minor cases which can now be diagnosed) the results of the future may be a good deal less gloomy.

Intestinal Intubation

DECOMPRESSION of the obstructed small intestine by aspiration through swallowed tubes is a valuable and widely used measure. Like all potent remedies in medicine it has its snags and dangers. The intestine is intubated with more difficulty than the stomach because the pylorus often refuses to pass the bulky tip of a Miller-Abbott or similar tube. The substitution of a bag containing mercury for the more usual air balloon on the end of these long tubes is one of the devices used to facilitate their transmission through the pylorus, and HARRIS and GORDON[1] have lately recorded their experiences with such a tube. Its advantages are that, as it requires only one lumen, the whole diameter of the tube can be used for its primary purpose of aspiration, and that it passes the pylorus more easily than its double-lumen predecessors, especially if, once its tip is in the stomach, it is left to descend spontaneously and unaided by well-intentioned hands. Rupture of the bag containing the mercury in 4 cases caused HARRIS and GORDON some alarm, but those familiar with the writings of the late Dr. THOMAS DOVER[2] will recall his habit of prescribing metallic mercury in daily doses of an ounce for a variety of disorders, and will know that mercury in the intestine seemed to do his patients no harm. One of them, Captain COLT, writing about the year 1740, estimated that he had swallowed 120 lb. of quicksilver over a period of nine years, with complete relief of his gout!

The usual trouble with an intestinal tube is that it will not go far enough; but on occasion it may go too far. Not only is a tube whose tip lies in the colon useless for decompressing the small intestine, but apparently it may irritate the small intestine to the point of aggravating the ileus it is supposed to relieve. In our present issue Dr. FRANK reports an extraordinary case in which the balloon of a 10 ft. tube was seen at the anus when over 3 ft. of the suction end still protruded from the nose; the patient's ileus passed off spontaneously when the tube was removed per rectum. HARRIS and GORDON advise that if a long tube passes through the ileocæcal valve it should be cut off at the nose and left to be evacuated per rectum, since attempts to pull it back may damage the bowel. They think that the position of the tip of a tube should be checked by X-ray examination when the 3 ft. mark has reached the nose, and that only 2–3 ft. of tube in the sma
intestine is needed for satisfactory decompressio
They believe that 6 ft. is the proper length for
intestinal tube. A curious difficulty they encountere
was swelling of the mercury-filled bag in tubes whi
remained in situ a long time—a swelling due to t
permeability of rubber to carbon dioxide. In a singl
lumen tube the added carbon dioxide cannot
evacuated and may make it impossible to wit
draw the tube. On three such occasions the tu
passed per rectum, but in a fourth case operatio
was required. POOL[3] has recorded another curio
occurrence, in a patient with a gastro-enterostom
A long tube was passed into the jejunum via th
duodenum, re-entered the stomach through th
artificial stoma, and continued on this merry-go-roun
for three revolutions, knotting itself in the process
It had to be removed by operation. (The case of th
disappearing mercury bougie, recorded on anothe
page, is simple compared with these others, bu
none the less instructive to those who use such things.

None of the papers mentioned deal with the ra
pressure necrosis which long residence of a tube ma
cause in the nose, behind the larynx, or above th
cardia; nor do they refer to the slight but definit
interference with post-anæsthetic coughing. Th
biochemical difficulties which the body encounter
through continuous removal of gastro-intestinal juice
must also be reckoned on the debit side. Thoug
undoubtedly a great blessing, intestinal aspiratio
is by no means foolproof.

Annotations

HOW TO TEACH HEALTH PRINCIPLES

CONVINCING arguments are wasted on those who choose not to hear them. Dr. Iago Galdston,[4] reviewing the history of health education, recalls the early antituberculosis campaigns, in which plain facts given as starkly as possible were expected to raise standards of sanitation and cleanliness. But people were not really interested—partly, as he points out, because this was disease education rather than health education. An era of jolly little health rhymes and animated cartoons has followed, and is doing rather better: but these too fail with most people because they are minatory and instructive. They try to condition the reader to better habits; but it is impossible to condition anyone whose interests are not in some way engaged. Pavlov's dog, when his mouth watered in obedience to the bell, was interested in his dinner; but health education has no immediate appeal to any of the body's instincts. Dr. Galdston thinks that nobody except a hypochondriac "wants" health in a positive way; the ordinary person wants not to be bothered by bad health and wants to take his good health for granted without having to think about it. He also wants many things for which good health is essential—to eat, move, rest, and serve his body's needs—but he puts them first and health nowhere, for he will often pursue them at the expense of health. Though the growing boy will govern and direct his appetite when he is in training, he does it not on account of any abstract ideal of health but because he wants his side to win.

Well then, Dr. Galdston suggests, we must approach people through their living interests if we want to improve their health. Unfortunately he does not give

many examples of what he thinks might be done, though he quotes an example of what should not. An American social-hygiene booklet addressed to high-school students gives a good deal about syphilis and gonorrhœa, remarks that syphilis may be transmitted by kissing, and says that "heavy necking" may lead to venereal infection. Grim and forceful pictures illustrate the text. But the inmates of high schools are not really interested in venereal disease: and they know that kissing does not lead to venereal disease—anyhow in their experience—and that necking leads to marriage more often than to infection. The effect of propaganda of this kind on most Americans, he says, is to provoke the vulgar, but sound, expression "I say it's spinach and to hell with it." A social-hygiene pamphlet for the high-school population should, in Dr. Galdston's opinion, be reassuring and constructive. It should tell them that the stirrings of youth, with their associated confusion and embarrassment, are the precursors of adult opportunities, achievement, and satisfactions. It should explain that many of the fears of the young are based on superstition and misconception, naming them only to discredit them. It should give sound advice on the way youngsters might deal with their behaviour problems, and prepare themselves for the adventure of adult life. Venereal diseases would be mentioned somewhere, but as conditions which hinder and interrupt progress towards youth's goals. "Youth," he says, "is interested in the adventure of living, in love and in achievement."

That it is normal to fall harmlessly in and out of love in the 'teens has never been generally admitted in Great Britain. We continue to segregate our adolescents into rigidly homosexual communities, and to tell them they are interested in games and Girl Guiding when in fact they are not. Some of them, thanks to our insistence, get permanently bent out of the true. The frank American approach has much to recommend it.

FATHER'S BLOOD IS BAD FOR MOTHER

WHEN a mother needs a blood-transfusion after labour it is quite a common practice to take her husband's blood if he happens to be in the same ABO and Rh groups as his wife. According to Chown,[1] this may lead to trouble later, and he gives details of the following example, under the striking heading "Never Transfuse a Woman with her Husband's Blood."

Mr. X and Mrs. X were both group O and Rh-positive. After the birth of their second child—a normal girl, also group O and Rh-positive—Mrs. X received a blood-transfusion from her husband and another from a different group-O Rh-positive donor. Her third pregnancy, three years later, resulted in a macerated male fœtus born at 5 months. Her fourth pregnancy produced a group-O Rh-positive full-term boy, and, to everyone's surprise, this child had erythroblastosis fœtalis of the generalised œdema type, from which he died. How and why had this unforeseen tragedy occurred? The possibilities were fully explored. The baby's red cells gave a strongly positive Coombs reaction, indicating that they had been exposed to and had adsorbed an immune body. The mother's serum contained an antibody that agglutinated the red cells of both the baby and her husband. So it was clear that the bloods of Mr. X and Baby X were antigenic for Mrs. X—yet all three were group O and Rh-positive. The next step was to find out whether there were differences in the Rh subgroups of these three, for the report "Rh-positive" only means that the cells were "D-positive," and incompatibilities of the two other factors, C and E, have caused trouble from time to time. However, this did not work out either. The Rh types of mother and baby were identical: the father's was different: so the antibody in the mother's blood that agglutinated the baby's red cells could not have anything to do with the Rh system at all. Matters seemed to have reached an impasse, but eventually the peccant factor was identified as the "Kell factor," described by Coombs et al.[2] in 1946.

The lessons that Chown draws from this incident are: first, that though we cannot make routine examinations for blood-groups outside the ABO and Rh systems, other factors do exist and sometimes cause incompatibility reactions; and second, that to transfuse a woman with her husband's blood is the one certain way to ensure that she will be sensitised to any unusual blood factor that a future baby may inherit, thus enhancing the risk that erythroblastosis will occur in the offspring. If a woman of childbearing age needs a transfusion, there is nearly always time to find out her Rh group, and so avoid giving Rh-positive blood to an Rh-negative woman; and it is usually possible to get blood from someone other than her husband. Chown says that, in his experience in Canada, about 20% of pregnant Rh-negative women with Rh antibodies in their blood had received previous transfusions, mostly after marriage. It is thus clear that these simple precautions are not being observed as rigidly as they ought to be, and that careful attention to them would reduce the incidence of erythroblastosis.

At this time of the year, when Father has been stripped of all else by his family, it may comfort him to know that at least he can keep his blood.

CONVALESCENT HOMES

THE National Health Service has shown up a shortage of beds for convalescence. The demand for convalescent treatment has grown, certainly; but some of the difficulty may be caused by changes in the status of homes. Before the Act nearly all convalescent homes were voluntary, and open either to all suitable comers or to patients sent by the home's parent hospital. Today some of the homes belong to the State and are fully open to N.H.S. patients; some are independent but have "contractual relations" with the regional board by which they receive patients without charging them anything; and some are independent, and not related to the service in any way. Whether this rearrangement is responsible or not, almoners now find it very difficult indeed to get beds for convalescent patients. The problem is complicated by the fact that the patients go from a large number of hospitals to a large number of homes; and the almoners are thus engaged in an endless game of "general post." It is not at all certain that the best use is made of the beds available, nor is it clear what types of convalescent homes are scarce or how scarce they are.

A year or two ago King Edward's Hospital Fund for London[3] issued a directory of convalescent homes serving London, intended to help almoners to find the one most suited to any given patient; but this is not enough, and the Fund is now preparing to study the whole problem thoroughly. A small committee has been set up to survey convalescence needs in the Metropolitan regions. Patients seeking admission come mainly, but by no means entirely, from hospital, and as a first step the almoners of 20 hospitals have been asked to give a brief report on all patients seeking convalescence—saying why they needed it, whether they got it, and if so where and when. Doctors at these hospitals will be asked to let the almoners know the name of every patient who in their opinion needs convalescence, even when they know from experience that there is nowhere suitable for him to go. It should

time to become fully effective. Since the risk of these complications is greatest in the first four weeks and thereafter decreases rapidly, the prospects for such treatment influencing prognosis are bright. This form of treatment cannot be undertaken in the patient's home and is possible only in a hospital with sufficient laboratory resources. The necessary estimations of prothrombin-time with a daily control require particular care and involve dangers for the unwary. This raises the question whether myocardial infarction should not be regarded as an indication for urgent admission to hospital. With prompt hospital treatment (not to mention inclusion of the many more minor cases which can now be diagnosed) the results of the future may be a good deal less gloomy.

Intestinal Intubation

DECOMPRESSION of the obstructed small intestine by aspiration through swallowed tubes is a valuable and widely used measure. Like all potent remedies in medicine it has its snags and dangers. The intestine is intubated with more difficulty than the stomach because the pylorus often refuses to pass the bulky tip of a Miller-Abbott or similar tube. The substitution of a bag containing mercury for the more usual air balloon on the end of these long tubes is one of the devices used to facilitate their transmission through the pylorus, and HARRIS and GORDON[1] have lately recorded their experiences with such a tube. Its advantages are that, as it requires only one lumen, the whole diameter of the tube can be used for its primary purpose of aspiration, and that it passes the pylorus more easily than its double-lumen predecessors, especially if, once its tip is in the stomach, it is left to descend spontaneously and unaided by well-intentioned hands. Rupture of the bag containing the mercury in 4 cases caused HARRIS and GORDON some alarm, but those familiar with the writings of the late Dr. THOMAS DOVER[2] will recall his habit of prescribing metallic mercury in daily doses of an ounce for a variety of disorders, and will know that mercury in the intestine seemed to do his patients no harm. One of them, Captain COLT, writing about the year 1740, estimated that he had swallowed 120 lb. of quicksilver over a period of nine years, with complete relief of his gout!

The usual trouble with an intestinal tube is that it will not go far enough; but on occasion it may go too far. Not only is a tube whose tip lies in the colon useless for decompressing the small intestine, but apparently it may irritate the small intestine to the point of aggravating the ileus it is supposed to relieve. In our present issue Dr. FRANK reports an extraordinary case in which the balloon of a 10 ft. tube was seen at the anus when over 3 ft. of the suction end still protruded from the nose; the patient's ileus passed off spontaneously when the tube was removed per rectum. HARRIS and GORDON advise that if a long tube passes through the ileocæcal valve it should be cut off at the nose and left to be evacuated per rectum, since attempts to pull it back may damage the bowel. They think that the position of the tip of a tube should be checked by X-ray examination when the 3 ft. mark has reached the nose, and that only 2–3 ft. of tube in the small intestine is needed for satisfactory decompression. They believe that 6 ft. is the proper length for an intestinal tube. A curious difficulty they encountered was swelling of the mercury-filled bag in tubes which remained in situ a long time—a swelling due to the permeability of rubber to carbon dioxide. In a single-lumen tube the added carbon dioxide cannot be evacuated and may make it impossible to withdraw the tube. On three such occasions the tube passed per rectum, but in a fourth case operation was required. POOL[3] has recorded another curious occurrence, in a patient with a gastro-enterostomy. A long tube was passed into the jejunum via the duodenum, re-entered the stomach through the artificial stoma, and continued on this merry-go-round for three revolutions, knotting itself in the process. It had to be removed by operation. (The case of the disappearing mercury bougie, recorded on another page, is simple compared with these others, but none the less instructive to those who use such things.)

None of the papers mentioned deal with the rare pressure necrosis which long residence of a tube may cause in the nose, behind the larynx, or above the cardia; nor do they refer to the slight but definite interference with post-anæsthetic coughing. The biochemical difficulties which the body encounters through continuous removal of gastro-intestinal juices must also be reckoned on the debit side. Though undoubtedly a great blessing, intestinal aspiration is by no means foolproof.

HOW TO TEACH HEALTH PRINCIPLES

CONVINCING arguments are wasted on those who choose not to hear them. Dr. Iago Galdston,[4] reviewing the history of health education, recalls the early antituberculosis campaigns, in which plain facts given as starkly as possible were expected to raise standards of sanitation and cleanliness. But people were not really interested—partly, as he points out, because this was disease education rather than health education. An era of jolly little health rhymes and animated cartoons has followed, and is doing rather better: but these too fail with most people because they are minatory and instructive. They try to condition the reader to better habits; but it is impossible to condition anyone whose interests are not in some way engaged. Pavlov's dog, when his mouth watered in obedience to the bell, was interested in his dinner; but health education has no immediate appeal to any of the body's instincts. Dr. Galdston thinks that nobody except a hypochondriac "wants" health in a positive way; the ordinary person wants not to be bothered by bad health and wants to take his good health for granted without having to think about it. He also wants many things for which good health is essential—to eat, move, rest, and serve his body's needs—but he puts them first and health nowhere, for he will often pursue them at the expense of health. Though the growing boy will govern and direct his appetite when he is in training, he does it not on account of any abstract ideal of health but because he wants his side to win.

Well then, Dr. Galdston suggests, we must approach people through their living interests if we want to improve their health. Unfortunately he does not give many examples of what he thinks might be done, though he quotes an example of what should not. An American social-hygiene booklet addressed to high-school students gives a good deal about syphilis and gonorrhœa, remarks that syphilis may be transmitted by kissing, and says that "heavy necking" may lead to venereal infection. Grim and forceful pictures illustrate the text. But the inmates of high schools are not really interested in venereal disease; and they know that kissing does not lead to venereal disease—anyhow in their experience—and that necking leads to marriage more often than to infection. The effect of propaganda of this kind on most Americans, he says, is to provoke the vulgar, but sound, expression "I say it's spinach and to hell with it." A social-hygiene pamphlet for the high-school population should, in Dr. Galdston's opinion, be reassuring and constructive. It should tell them that the stirrings of youth, with their associated confusion and embarrassment, are the precursors of adult opportunities, achievement, and satisfactions. It should explain that many of the fears of the young are based on superstition and misconception, naming them only to discredit them. It should give sound advice on the way youngsters might deal with their behaviour problems, and prepare themselves for the adventure of adult life. Venereal diseases would be mentioned somewhere, but as conditions which hinder and interrupt progress towards youth's goals. "Youth," he says, "is interested in the adventure of living, in love and in achievement."

That it is normal to fall harmlessly in and out of love in the 'teens has never been generally admitted in Great Britain. We continue to segregate our adolescents into rigidly homosexual communities, and to tell them they are interested in games and Girl Guiding when in fact they are not. Some of them, thanks to our insistence, get permanently bent out of the true. The frank American approach has much to recommend it.

FATHER'S BLOOD IS BAD FOR MOTHER

When a mother needs a blood-transfusion after labour it is quite a common practice to take her husband's blood if he happens to be in the same ABO and Rh groups as his wife. According to Chown,[1] this may lead to trouble later, and he gives details of the following example, under the striking heading "Never Transfuse a Woman with her Husband's Blood."

Mr. X and Mrs. X were both group O and Rh-positive. After the birth of their second child—a normal girl, also group O and Rh-positive—Mrs. X received a blood-transfusion from her husband and another from a different group-O Rh-positive donor. Her third pregnancy, three years later, resulted in a macerated male fœtus born at 5 months. Her fourth pregnancy produced a group-O Rh-positive full-term boy, and, to everyone's surprise, this child had erythroblastosis fœtalis of the generalised œdema type, from which he died. How and why had this unforeseen tragedy occurred? The possibilities were fully explored. The baby's red cells gave a strongly positive Coombs reaction, indicating that they had been exposed to and had adsorbed an immune body. The mother's serum contained an antibody that agglutinated the red cells of both the baby and her husband. So it was clear that the bloods of Mr. X and Baby X were antigenic for Mrs. X—yet all three were group O and Rh-positive. The next step was to find out whether there were differences in the Rh subgroups of these three, for the report "Rh-positive" only means that the cells were "D-positive," and incompatibilities of the two other factors, C and E, have caused trouble from time to time. However, this did not work out either. The Rh types of mother and baby were identical: the father's was different: so the antibody in the mother's blood that agglutinated the baby's red cells could not have anything to do with the Rh system at all. Matters seemed to have reached an impasse, but eventually the peccant factor was identified as the "Kell factor," described by Coombs et al.[2] in 1946.

The lessons that Chown draws from this incident are: first, that though we cannot make routine examinations for blood-groups outside the ABO and Rh systems, other factors do exist and sometimes cause incompatibility reactions; and second, that to transfuse a woman with her husband's blood is the one certain way to ensure that she will be sensitised to any unusual blood factor that a future baby may inherit, thus enhancing the risk that erythroblastosis will occur in the offspring. If a woman of childbearing age needs a transfusion, there is nearly always time to find out her Rh group, and so avoid giving Rh-positive blood to an Rh-negative woman; and it is usually possible to get blood from someone other than her husband. Chown says that, in his experience in Canada, about 20% of pregnant Rh-negative women with Rh antibodies in their blood had received previous transfusions, mostly after marriage. It is thus clear that these simple precautions are not being observed as rigidly as they ought to be, and that careful attention to them would reduce the incidence of erythroblastosis.

At this time of the year, when Father has been stripped of all else by his family, it may comfort him to know that at least he can keep his blood.

FATHER'S BLOOD IS BAD FOR MOTHER

WHEN a mother needs a blood-transfusion after labour it is quite a common practice to take her husband's blood if he happens to be in the same ABO and Rh groups as his wife. According to Chown,[1] this may lead to trouble later, and he gives details of the following example, under the striking heading "Never Transfuse a Woman with her Husband's Blood."

Mr. X and Mrs. X were both group O and Rh-positive. After the birth of their second child—a normal girl, also group O and Rh-positive—Mrs. X received a blood-transfusion from her husband and another from a different group-O Rh-positive donor. Her third pregnancy, three years later, resulted in a macerated male fœtus born at 5 months. Her fourth pregnancy produced a group-O Rh-positive full-term boy, and, to everyone's surprise, this child had erythroblastosis fœtalis of the generalised œdema type, from which he died. How and why had this unforeseen tragedy occurred? The possibilities were fully explored. The baby's red cells gave a strongly positive Coombs reaction, indicating that they had been exposed to and had adsorbed an immune body. The mother's serum contained an antibody that agglutinated the red cells of both the baby and her husband. So it was clear that the bloods of Mr. X and Baby X were antigenic for Mrs. X—yet all three were group O and Rh-positive. The next step was to find out whether there were differences in the Rh subgroups of these three, for the report "Rh-positive" only means that the cells were "D-positive," and incompatibilities of the two other factors, C and E, have caused trouble from time to time. However, this did not work out either. The Rh types of mother and baby were identical; the father's was different: so the antibody in the mother's blood that agglutinated the baby's red cells could not have anything to do with the Rh system at all. Matters seemed to have reached an impasse, but eventually the peccant factor was identified as the "Kell factor," described by Coombs et al.[2] in 1946.

The lessons that Chown draws from this incident are: first, that though we cannot make routine examinations for blood-groups outside the ABO and Rh systems, other factors do exist and sometimes cause incompatibility reactions; and second, that to transfuse a woman with her husband's blood is the one certain way to ensure that she will be sensitised to any unusual blood factor that a future baby may inherit, thus enhancing the risk that erythroblastosis will occur in the offspring. If a woman of childbearing age needs a transfusion, there is nearly always time to find out her Rh group, and so avoid giving Rh-positive blood to an Rh-negative woman; and it is usually possible to get blood from someone other than her husband. Chown says that, in his experience in Canada, about 20% of pregnant Rh-negative women with Rh antibodies in their blood had received previous transfusions, mostly after marriage. It is thus clear that these simple precautions are not being observed as rigidly as they ought to be, and that careful attention to them would reduce the incidence of erythroblastosis.

At this time of the year, when Father has been stripped of all else by his family, it may comfort him to know that at least he can keep his blood.

CONVALESCENT HOMES

THE National Health Service has shown up a shortage of beds for convalescence. The demand for convalescent treatment has grown, certainly; but some of the difficulty may be caused by changes in the status of homes. Before the Act nearly all convalescent homes were voluntary, and open either to all suitable comers or to patients sent by the home's parent hospital. Today some of the homes belong to the State and are fully open to N.H.S. patients; some are independent but have "contractual relations" with the regional board by which they receive patients without charging them anything; and some are independent, and not related to the service in any way. Whether this rearrangement is responsible or not, almoners now find it very difficult indeed to get beds for convalescent patients. The problem is complicated by the fact that the patients go from a large number of hospitals to a large number of homes; and the almoners are thus engaged in an endless game of "general post." It is not at all certain that the best use is made of the beds available, nor is it clear what types of convalescent homes are scarce or how scarce they are.

A year or two ago King Edward's Hospital Fund for London[3] issued a directory of convalescent homes serving London, intended to help almoners to find the one most suited to any given patient; but this is not enough, and the Fund is now preparing to study the whole problem thoroughly. A small committee has been set up to survey convalescence needs in the Metropolitan regions. Patients seeking admission come mainly, but by no means entirely, from hospital, and as a first step the almoners of 20 hospitals have been asked to give a brief report on all patients seeking convalescence—saying why they needed it, whether they got it, and if so where and when. Doctors at these hospitals will be asked to let the almoners know the name of every patient who in their opinion needs convalescence, even when they know from experience that there is nowhere suitable for him to go. It should

thus be possible to ascertain which categories of patient most need convalescence and to what extent their needs are met. Other agencies sending patients for convalescence or recuperative holidays include county health authorities, friendly societies, and large business firms; and a selection of these, too, are being asked to state their needs and to say how far they are satisfied. At the same time a study is to be made of those actually reaching convalescent homes. A large number of homes will be asked how many patients they receive over a given period, and into what categories they fall. The answers should show how many patients get into convalescent homes, where they come from, and what is their state of health on admission.

---

[2] Coombs, R. R. A., Mourant, A. E., Race, R. R. *Lancet*, 1946, i, 246.

[3] See *Lancet*, 1949, i, 577.

It should be possible to complete a reasonably accurate survey within a year, and the Fund will then be able to issue a report for the guidance of those whose duty it is to maintain homes. It will also go on helping to establish new homes by making grants of money. Thanks largely to its financial help, several homes have been set up already to take the types of case for which accommodation is scarce. The most notable of these are perhaps Capesthorne, at Mudeford, which is run by the Red Cross for babies under the age of 2, and a small home for epileptics at Fairwarp in Sussex, run by the National Association for Mental Health. The Fund is also giving support to a new home for epileptics, shortly to be opened by the N.A.M.H. at Saxmundham, and to a new wing of the Dedisham Convalescent Nursery School for children under 5. These are a beginning, but before any large programme can be planned it is essential to know accurately what types of home are most needed. This the survey should reveal.

CARCINOMA AS A SEQUEL TO ULCERATIVE COLITIS

ONE of the most serious complications of ulcerative colitis is carcinoma of the colon or rectum. This is certainly rare, though the incidence varies widely in different series. Johnson and Orr[1] put the figure at about 2·5%. The highest incidence is recorded by Jackman and colleagues[2] in 95 patients who developed ulcerative colitis before the age of 16 years; 6·5% of these children developed carcinomas of the large bowel in later life. The duration of symptoms of ulcerative colitis before the carcinoma is diagnosed varies in the reported cases from 3 months to 36 years; the average duration has been given by Cattell and Sachs[3] as 9 years. In patients with ulcerative colitis, carcinomas of the colon and rectum seem to arise, on average, at an earlier age than in the general run of patients. Thus Johnson and Orr found that in 40 recorded cases of carcinoma complicating ulcerative colitis the average age at onset was 40·2 years, compared with 53 years in other cases of carcinoma coli.

A much more common complication of ulcerative colitis is the formation of polypi, which are seen in 10–16% of most series. They arise in severe cases during the healing phases and are most numerous in the rectum, getting less frequent higher up. They have sometimes been observed in the lower part of the ileum. In view of the known tendency of intestinal polypi to become malignant, it is sometimes suggested that they are the precursors of carcinoma in patients with ulcerative colitis. In considering this question the pathology of the polypi must be clearly understood. Most of them are inflammatory in origin and consist of œdematous hypertrophic areas of mucosa which have escaped the destruction suffered by the surrounding areas. Microscopically, beneath a generally intact layer of lining epithelial cells the tissues are infiltrated with inflammatory cells with an increase of fibrous tissue. Some of the glands may become blocked, leading to retention of mucus and the formation of cysts. These so-called pseudoadenomatous polypi must be distinguished from true adenomatous polypi. The adenomatous type is occasionally found in patients with ulcerative colitis and may become malignant. But Felson and Wolarsky[4] have found that out of 955 patients of varying ages who came to necropsy, excluding cases of ulcerative colitis, 6·4% had two or more adenomatous polypi in the colon. (This does not include the rarer hereditary adenomatosis coli, in which the whole colon is studded with multiple adenomas.) The incidence of adenoma in their patients with ulcerative colitis was well below this figure. Polypi of the pseudoadenomatous type were seen in 134 (15·7%) of their 855 patients with ulcerative colitis. In no case did they note any tendency for the polypi to become malignant. These findings must be taken as evidence against the polyposis of ulcerative colitis being a pre-malignant condition; and it must be concluded that the presence of such polypi is not an indication for colectomy.

THE LIVER LOBULE IN PERSPECTIVE

FOR a century misconception of the histological structure of the liver has been copied from textbook to textbook (with a few exceptions); and this despite the embryological studies of the latter half of the century and the more recent large volume of experimental work on the ætiology of hepatic cirrhosis. The picture familiar to all—the liver lobule composed of anastomosing cords or columns of cells radially arranged around the central vein—was conceived by Gerlach in 1849, developed chiefly by Beale (1856, 1889), and supported by Pflüger (1869); the description, analysis, and reassertions of Hering (1866, 1872) on the geometric three-dimensional aspect were almost completely ignored. So a good many modern textbooks still give only the one-dimensional account.

It was the preparation of a stereoscopic filmstrip on the histology of the liver for anatomy students that stimulated Elias[5] to re-examine the structure of the liver lobule. Having completed stereograms of liver lobules he wanted to add photographs of wax-plate reconstruction models and also some photomicrographs. When he came to examine sections of the human liver made perpendicularly to the central lobular vein he noted that long rows of cells were invariably seen and were unaccountably numerous. For he reasoned that if there were tortuous but linear columns arranged *radially* about the central vein, the chances of the microtome cutting them lengthwise for any considerable distance would be very slight; most of them would be cut obliquely and would be about three to four cells long. Further, it was almost impossible to find cross-sections of cords, which should be very numerous in tangential sections of the lobule. In man and the cat, sections parallel to the central vein showed long rows of cells simulating cords, and, no matter how the human or cat liver was cut, long linear rows of cells were always seen, with, at wide intervals, small isolated groups of cells in an epithelial arrangement. Elias concluded that this appearance in sections could only be produced by curved plates, sheets, or laminæ, *one cell thick*. This was verified by making wax-plate reconstruction models and by examining thick unstained sections mounted in glycerin.

Thus the new concept is that the hepatic cell-plates are curved and perforated at short intervals to permit the passage of the sinusoids which run towards the central vein: the cell-plates have unicellular and sometimes bicellular bridges, and it is these which account for the appearance of cords on cross-section. The human hepatic lobule therefore consists of a continuous tissue of connected walls, which enclose the spaces for the sinusoids to run through. The polygonal meshwork of bile-capillaries runs between the cells in the plates and bridges, and it forms hexagonal intercellular and pericellular networks within the liver plates. This is in close accord with the easily demonstrable network commonly seen in sections, which fits poorly into the hitherto conventional picture. Since in man and the cat the spaces formed for the sinusoids between the plates are like long sacks, their type of liver may be regarded as "saccular," in contrast to the "tubular" type of liver of the horse and rabbit, in which the spaces between the hepatic laminæ are narrow and cylindrical.

NEW CONCEPTIONS IN HIRSCHSPRUNG'S DISEASE

ANOTHER year's work on Hirschsprung's disease here and in the U.S.A. has confirmed the views on its pathology and treatment which Dr. Bodian and his colleagues[1] at the Hospital for Sick Children, Great Ormond Street, set out in their paper of January, 1949. At that time clinical evidence had placed the site of intestinal obstruction in a narrow "spastic" segment distal to the dilated hypertrophied colon. A careful radiological technique had been developed to display the terminal narrow segment and to obviate the flooding of the lower colon with barium which produces a fallacious appearance of dilatation to the anus. Resection of this abnormal distal segment by rectosigmoidectomy had been reported, first by Swenson,[2] of Boston, to the Society of University Surgeons at New Orleans, and then by Stephens,[3] one of the Great Ormond Street team, to the surgical section of the Royal Society of Medicine. Histological examination of the distal segment by Bodian in 15 cases had revealed an absence of intramural ganglion cells and the presence of abnormal nerve-trunks at the sites of Auerbach's and Meissner's plexuses.

Early in 1949, Whitehouse and Kernohan[4] published a pathological report on 11 cases of Hirschsprung's disease from the Mayo Clinic; 10 of the specimens were obtained at necropsy and 1 after subtotal colectomy; 8 of the patients were children aged 8 months to 15 years, and 3 were adults. The histological findings were essentially the same as those reported by Bodian et al. During 1949 Swenson and his collaborators[5] amplified their former clinical and radiological reports by a study of colonic peristalsis in 8 cases of Hirschsprung's disease, using a multiple balloon technique, and by a histological study of 7 specimens. They also reported on a total of 34 rectosigmoidectomy operations. Their physiological experiments proved that peristalsis is absent and tonus increased in the distal colonic segment, and they confirmed that there are no sympathetic ganglion cells in this part of the gut. Their follow-up results for periods up to two years were apparent cures in 33 cases and 1 postoperative death. Radiologically they demonstrated return of the colon to approximately normal after operation.

In this issue (p. 19) Dr. Bodian, Mr. Stephens, and Dr. Ward bring their findings and results up to date. The number of children with Hirschsprung's disease treated by rectosigmoidectomy at the Hospital for Sick Children is now 26, and the 12 cases which were formerly reported have now been observed for twelve to fifteen months. This is still too short a time to reveal the final effects of the treatment, but the clinical improvement in the children, the establishment of regular spontaneous bowel actions, and the striking regression of radiological appearances after operation are impressive. The histological findings previously described have now been established in 28 consecutive cases; there can be no reasonable doubt that they are characteristic of Hirschsprung's disease and that absent peristaltic movement and increased tone in the distal colonic segment are functional manifestations of these structural changes. On the basis of the new ætiological concept rectosigmoidectomy is a rational treatment, and its value is certainly supported by the results so far obtained.

NOTIFICATION OF INFECTIOUS DISEASES

THE classification of notifiable diseases of the central nervous system has now been placed on a more realistic basis. By new regulations, which we outlined last week, the distinction of polioencephalitis from poliomyelitis has been brought to an end; and poliomyelitis is now notifiable as "paralytic" or "non-paralytic." "Acute encephalitis" ("infective" or "post-infectious") replaces the former heading of "encephalitis lethargica"; and the more generic "meningococcal infection" supersedes "cerebrospinal fever." The regulations are discussed in our public-health columns this week.

NEW YEAR HONOURS

Dr. Haden Guest, who receives a peerage, entered Parliament first in 1923 and is chairman both of the House of Commons Medical Parliamentary Group and of the Medical Personnel (Priority) Committee. He founded the Labour Party's Commonwealth Group, and the breadth and vitality of his interests have likewise been shown by contributions to our columns as a special correspondent abroad in war and peace, as well as by regular parliamentary notes from "Medicus, M.P." over many years. We thus have special reason to be glad at this recognition of his public services and personal merits. The knighthood in the Royal Victorian Order bestowed on Dr. H. K. Graham-Hodgson, of the Middlesex Hospital, is a suitable promotion from the C.V.O. he received as the radiological member of the team who attended King George V in his illness of 1928. Mr. T. E. V. Hurley, who becomes K.B.E., is consulting surgeon to the Royal Melbourne Hospital, and of the new knights bachelor two (Dr. F. A. Gunasekera, of Ceylon, and Mr. T. G. Wilson, of Adelaide) are distinguished members of our profession overseas. At home it is a pleasure to see the name of Dr. H. E. A. Boldero, dean of the Middlesex Hospital medical school and registrar of the Royal College of Physicians, whose wisdom in counsel has been decisive so much more often than his modest demeanour would suggest. Dr. J. A. Charles, who will next May succeed Sir Wilson Jameson as chief medical officer of the Ministry of Health, is another quietly effective man, whose ability was evident when he was medical officer of health for Newcastle upon Tyne, and who, as a deputy C.M.O. at the Ministry, has won confidence by his readiness to listen and his power to understand. Our colleagues in Northern Ireland will especially welcome the honour paid to Dr. W. W. D. Thomson, professor of medicine at Queen's University since 1923, and one of those who have helped to make Belfast the outstanding school it is today.

These and the other names on a good list appear in full on another page. Outside the Medical Register, one of the highest honours, the G.C.B., goes to Sir William Douglas, secretary to the Ministry of Health during its difficult labours of the past few years, and a knighthood to Mr. Arthur Sims, benefactor of medicine and surgery through his Commonwealth travelling professorships.

CONTROL OF INFECTION WITH THE BOVINE TUBERCLE BACILLUS*

JOHN FRANCIS
B.Sc., M.R.C.V.S.

In the control of human or bovine tuberculosis the ultimate object is to prevent tubercle bacilli entering the lung. The measures which have to be taken to achieve this are far from simple, and because of differences in the pathogenesis of human and bovine tuberculosis, and differences in the value placed on human and animal life, very different methods are used in man and cattle.

PATHOGENESIS AND NATURAL HISTORY

The striking fact about primary tuberculous infection in man is that as a rule the lesions heal, giving rise to "the familiar non-progressive globular little lesions of the primary complex." Hence a large proportion of the population reacts to the tuberculin test but does not spread infection. It is the person with bronchogenic phthisis of the "reinfection type" who chiefly spreads the disease.

In cattle the position is quite different. Only about 20% of British cattle react to the tuberculin test, but almost all of these have "open," though not acute, pulmonary tuberculosis of the bronchogenic type.

This difference between man and cattle has long been obvious, but our knowledge of bovine pulmonary tuberculosis has been put on a much firmer basis by Stamp (1948). It appears that when either calves or adult cattle become infected for the first time, by the aerogenous route, the result is usually a slowly progressive bronchopneumonia; and reinfection, either endogenous or exogenous, also gives rise to a bronchopneumonia. Calves which are housed with cows are exposed to a constant risk of infection by the aerogenous route, but when calves are not housed with cows about 90% of them reach maturity (two years) without being infected. (This is usually true even if they are pastured with cows, for the danger of infection at pasture is far less than in the cowshed.) Beef cattle are killed at two or three years, and figures obtained at meat-inspection show that the incidence in these animals is only 5–15%. After parturition a heifer enters the cowshed and in many dairy-herds she is exposed to heavy aerogenous infection during the rest of her life.

Fig. 1 shows the average incidence of tuberculosis at various ages. The evidence indicates that the high incidence of tuberculosis in dairy-cows is caused by this exposure to aerogenous infection and their longer average life; there is no real evidence that the "strain of milk production and calf-bearing" lowers resistance to tuberculosis. In support of this view it may be mentioned that Wade (1942) and Burke (1940) have been unable to demonstrate that pregnancy and suckling influences the mortality of tuberculous rabbits.

The risk of calves being infected by milk is not great, for only about 1% of tuberculous cows have tuberculosis of the udder. On the other hand, where it does exist, udder tuberculosis is a grave danger because if one cow has the disease it may infect all the calves fed on the mixed milk of the herd.

INCIDENCE AND EPIDEMIOLOGY

In Great Britain there has been much confusion about the incidence of bovine tuberculosis, the figure of 40% being applied indiscriminately to "cows" and "cattle." It will be seen from fig. 1 that if the incidence in dairy-cows is 40% the incidence in all cattle is much lower. The most reliable estimate is that of Ritchie (1946):

	Cattle of all ages (%)	Cows (%)
England	20	—
Wales	7·5	—
Scotland	15	—
Great Britain	17–18	30–35

Assuming that "cattle" have an average age of 2·5 years and cows of 5 years it will be seen that the figures for Great Britain fit reasonably well on to the curve of age-incidence.

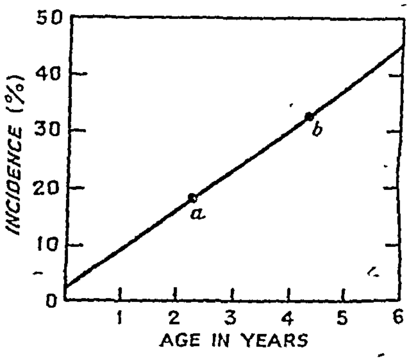

Fig. 1—Incidence of tuberculosis in cattle at various ages. The curve is based on information relating to Great Britain (Francis 1947). Point *a* shows the incidence of tuberculosis in all cattle, and point *b* the incidence in cows, as estimated by Ritchie (1946), and it will be seen that, presuming the average age of all cattle is $2^1/_4$ years and of all cows $4^1/_4$ years, these estimates fit on to the curve.

In his estimate Ritchie took account of the fact that there were then nearly a million cattle in officially tubercle-free herds. There are now $1^1/_2$ million cattle in attested herds and a considerable number in tuberculin-tested (T.T.)

Estimates of the economic loss from tuberculosis vary from £1 million to £3 million, but these only include the more obvious losses, and a better idea of the effect of tuberculosis can be obtained from the statement of Arthur (1948):

> "It is only when one has worked on a farm with an originally high reactor rate and then later on the same farm under identical conditions and with the same breed and type of animal—but free from tuberculosis—that one is fully conscious of the tremendous toll that this disease is exacting from the national economy in such a diversity of insidious and spectacular ways."

The course of the tuberculous epidemic clearly depends on two factors—the degree of exposure to infection and the resistance of those exposed. Krause (1928) has shown how tuberculosis must have increased with the early civilisations, where large numbers of people were crowded together in cities, decreased during the Middle Ages, and then reached a peak during the 17th century in London, followed by a steady decline beginning at the turn of the 18th century. Much the same may be true of bovine tuberculosis. It may have been introduced to Great Britain by Roman cattle, but under the conditions then prevailing it would have spread very little. It was probably introduced again during the 17th century with the Dutch cattle which helped to found our Shorthorn breed. The great success of the Shorthorns caused them to be crossed with most other local breeds, and British stock became fairly heavily tubercularised, so that when the famous beef and dairy herds were exported to the New World they, like the human beings, took tuberculosis with them. However, tuberculosis seldom reaches a high incidence in cattle kept in the open: it is only when they are housed, for intensive milk-production, that the incidence rises. Fig. 2A shows that in Great Britain, the incidence is highest in the areas supplying milk to the large cities, where farmers buy in cows to maintain their "flying" herds and thus provide every opportunity for the spread of infection.

There is no reason to think that the various European breeds of cattle differ in their susceptibility to tuberculosis; but the Zebu cattle of Africa and India have a considerably higher resistance, although, in Africa at least, they have not been exposed to tuberculosis for many hundreds of years.

RELATIONSHIP OF BOVINE AND HUMAN TYPES OF TUBERCLE BACILLUS

The bovine tubercle bacillus can produce disease in a very wide range of species: it is less specialised in its pathogenic properties, and therefore perhaps developmentally more primitive, than the human type.

In 1901 Koch expressed the opinion that it was not pathogenic to man; but the workers of the Royal Commission on Tuberculosis (Cobbett 1917), from epidemiological and pathological evidence, with experiments on monkeys, concluded that it was just as virulent for man as the human type. There must, however, be some reason for the existence of the human type of tubercle bacillus and some explanation of the fact that it is much commoner than the bovine type in the human lung. Griffith (1937) said that the rarity of bovine-type infection could not be due to a lesser invasive power. He pointed out that the bono and joint forms of tuberculosis are often produced by the bovine type which has gained entry by the difficult intestinal route. It may be, however, that the bovine tubercle bacillus has less power to establish itself in the human lung than has the human tubercle bacillus. It is well known that some pathogens have great powers of spread but produce a mild disease, whereas others have low infectivity but when once established are very lethal; and Lurie (1947) has shown that strains of rabbits can be produced which are resistant to infection but succumb rapidly when once infection is established, whereas others are easily infected but are resistant to the established disease. Pinner (1940) has described a similar phenomenon in man: the chances of a negro becoming tuberculous in a given environment are no greater than those of a white man, but the chances that the negro will die of his tuberculosis are three times greater. If these differences can exist in the host it does not seem unreasonable to assume that the bovine tubercle bacillus has less power of establishing itself in the lung than the human, but when once established is equally virulent.[1]

INFECTION OF MAN WITH THE BOVINE TUBERCLE BACILLUS

A small proportion of persons who ingest bovine tubercle bacilli in milk become ill with tuberculosis. This is the one form of human tuberculosis that can be easily prevented; so it is natural that there should be a great effort to obtain milk free from tubercle bacilli. But the quantitative aspect of the subject is usually neglected. Samples are described as infected or uninfected on the basis of a guineapig test, but the 1–5 bacilli which will infect a guineapig when given subcutaneously will usually fail to infect a child when given orally; Webber (1910) found that quite heavy infection often failed to produce disease in man. Ostermann (1908) thought that for milk to be safe for man, it must not contain more than 1000 tubercle bacilli per ml. This is hardly an acceptable "standard," but the intensity of infection is clearly very important. Even though the number of positive milk samples remains high in this country, the decrease in non-pulmonary tuberculosis in children (Lethem 1946) may indicate that veterinary inspection of herds has reduced the weight of infection.

Though Theobald Smith in 1898 drew attention to the risk of respiratory infection from cattle, this has had comparatively little attention in Great Britain, perhaps because most studies of human tuberculosis have dealt with town-dwellers (e.g., Blacklock 1932). In 1909 Griffith observed pulmonary tuberculosis in man due to the bovine type, but Griffith and Munro (1943) concluded that bovine-type infection was rarely acquired by contact with human cases or tuberculous cattle. Cutbill and Lynn (1944), who found 1·6% of bovine-type infection in 2004 cases of phthisis which had not been in contact with cattle, compared with 16·4% in 97 cases of phthisis which had been in contact with cattle, emphasised the possibility of respiratory transfer of the bovine bacillus from cattle to man, man to man, and man to cattle; but in general, British investigators seem to have been loth to accept the importance of direct inhalation infection with the bovine type. It has remained for the Scandinavians to make it abundantly clear that people who work with tuberculous cattle are exposed to a very real danger of direct aerogenous infection chiefly from the dust of the cowsheds.

Earlier work on this subject has been reviewed by Hedvall (1942) and Sigurdsson (1945).

Hedvall, in Sweden, described 67 cases of bovine pulmonary tuberculosis in man. Only 14 of the 67 cases were in persons living in towns, and of these several had acquired their infection during an earlier stay in the country. As there were rather more people in the urban than in the rural districts of the area studied, the rural population obviously ran a much

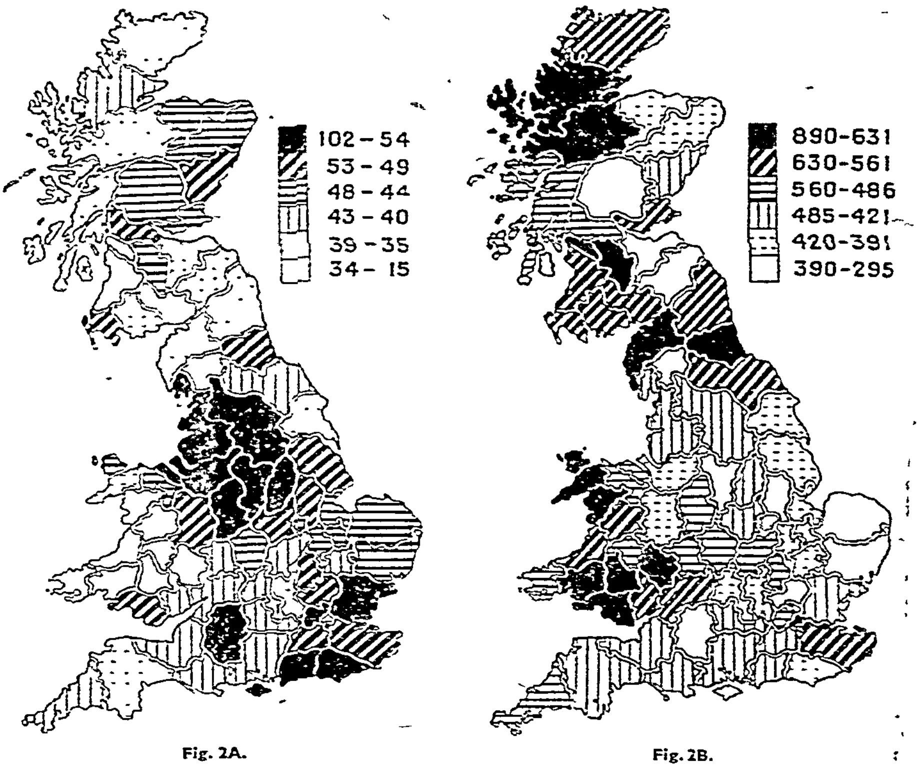

Fig. 2A. Fig. 2B.

Fig. 2—(A) Incidence of tuberculosis in cattle (combined bovine tuberculosis index Francis 1948a). (B) Tot mortality from tuberculosis in administrative counties (country districts) per million of population.

---

[1] There is some evidence that change of type from bovine to human may occur in the human lung (Francis 1950).

greater risk of bovine infection than the urban, the risk being much greater in veterinary surgeons, butchers, and farmers than in those country-dwellers not handling cattle. In 35 cases the route of infection was uncertain; in 12 the primary lesions appeared to be in the abdomen, and in 20 in the lung.

Sigurdsson (1945) made a detailed epidemiological study in Ribe county, Denmark. From 1932 to 1936 the average proportion of tubercle-free herds was 7·9%, and of 37 rural patients developing phthisis 57% were infected with the bovine type of tubercle bacillus. From 1937 to 1940 the average proportion of tubercle-free herds was 31·2% and of 64 cases of phthisis in rural patients 31% were of the bovine type. These figures are, of course, no more than suggestive.

After consultation with local veterinary surgeons a special investigation was carried out on 100 families who lived on farms with tuberculin-negative cattle, and 100 who lived on farms with strongly tuberculous herds. In the latter the proportion of tuberculin-positive persons increased steadily during childhood, reaching 75% at fifteen years, whereas in children on clean farms the proportion of reactors was only 15% at this age.

Sigurdsson concludes that the amount of bovine tuberculosis in human beings is directly related to the degree of tuberculosis in the herds with which they have been in contact. Mild disease associated with bovine-type infection appeared to originate by either the alimentary or aerogenous routes. All the severe cases of bovine phthisis seem to have developed by inhalation infection in the cowshed, and their condition was indistinguishable from those produced by the human type of tubercle bacillus. Sigurdsson found little evidence of bovine-type infection passing from man to man, but he did observe 6 cases in which infection was apparently transmitted from man to cattle: in 3 the type was human and in 3 bovine.

Griffith and Munro (1943) have shown that bovine-type pulmonary tuberculosis is commoner in Great Britain than was formerly believed, but no inquiry on the Scandinavian lines has been undertaken here. As Sigurdsson (1945) says, "extensive systematic investigations covering all forms of tuberculosis, urban patients as well as rural patients in all age classes, all social classes, all parts of the various countries, and performed in the proper proportion to the morbidity within these groups" must be made before a reliable picture can be obtained.

EFFECT OF TUBERCULOUS MILK ON THE EPIDEMIOLOGY OF HUMAN TUBERCULOSIS

I thought it might be of interest to see whether there is any obvious relation between the regional incidence of bovine tuberculosis in cattle and the regional death-rates from tuberculosis in man. Fig. 2A shows the combined bovine tuberculosis index (Francis 1948a), and fig. 2B the average tuberculosis death-rates for 1945 and 1946, in the "administrative counties"—i.e., in the whole of Great Britain except the large towns and urban areas.[2] The two maps reveal a remarkable inverse relation between the incidence of bovine tuberculosis and the death-rate from human tuberculosis, and one cannot help wondering whether exposure to tubercle bacilli in milk does not after all provide a protection against the more dangerous respiratory infection in later life. There is, indeed, other evidence that it does.

Bovine tuberculosis was common in South Jutland when Holm and Holm (1945) examined 9000 children of three to fourteen years and found that about one-third were tuberculin-positive. In Zeeland, which was free from bovine tuberculosis only about one-ninth of 4500 children were tuberculin-positive. But, although the proportion of tuberculin-positive children was three times higher in Jutland than in Zeeland, the proportion of children with X-ray lesions in their lungs was two and a half times higher in Zeeland than in Jutland, and in the tuberculin-positive eight times higher. Holm and Holm write: "It is safe to say that tuberculous milk infection protects the children against tuberculous infection of the lungs." In South Jutland 86% of the adults were tuberculin-positive and 1·16% radiographically positive; in Zeeland 78% of the adults were tuberculin-positive and 1·73% radiographically positive. In towns with tuberculous milk 75% of children were tuberculin-positive at fourteen years of age, whereas in towns with tubercle-free milk only 20% were tuberculin-positive; but there was no more clinical tuberculosis among children drinking the tuberculous milk than among those drinking the tubercle-free milk. From all this Holm and Holm conclude that bovine milk infection is fairly harmless except in small children, whereas inhalation infection, whether human or bovine, is much more dangerous. They draw attention to the grave danger to which adolescents from tubercle-free areas are exposed when they meet respiratory infection in the towns, and they advocate wide use of B.C.G., particularly in adolescents.

Madsen et al. (1942) examined nearly 3000 children in areas where tuberculosis occurred in cattle and 9000 in areas where it did not. The proportion who were tuberculin-positive was four times greater where there was bovine tuberculosis, but examination of hospital records showed that the proportion requiring treatment was twice as large in the regions where there was no bovine tuberculosis; and so was the proportion with X-ray changes in the lungs.

Since the maps for Great Britain were prepared, I have seen the report by Lichtenstein (1924) on his careful inquiry relating the tuberculosis death-rate in various age-groups in Sweden to the incidence of tuberculosis in cattle. He concluded that "thus far, Swedish statistics afford no proof whatsoever for the assumption that there is any noteworthy connexion between infantile tuberculosis and tuberculosis in cattle, but, on the contrary point in the direction that there is a similar connexion between infantile tuberculosis and tuberculosis among the population as a whole." The inverse relation between the incidence of human and bovine tuberculosis was, however, rather less striking than in Great Britain.

Various people have, of course, always believed that milk infection via the resistant alimentary route confers immunity against the more serious respiratory infection, and there is little doubt that they are right. On the other hand, those who advocate pasteurisation have pointed out that tubercle bacilli cannot be tolerated in milk as a means of immunisation, because they kill something like 1000 people a year. This likewise is true; but the Registrar-General's report shows that during 1945 2208 persons under fifteen years of age died of tuberculosis, and 4331 persons between fifteen and thirty. If removal of tubercle bacilli from milk is going to increase susceptibility and mortality in adolescents one is entitled to ask whether on balance it will benefit public health—unless more is done to protect this important age-group.

Having said this, I must make it perfectly clear that I am not opposed to pasteurisation of milk and believe that every effort should be made to eradicate tuberculosis from cattle. From the standpoint of public health the increase in milk-supplies which will follow eradication may well be more important than the removal of tubercle bacilli from milk. This removal will, however, prevent the deaths from bovine-type infection in children and I believe that the loss of the specific immunity formerly produced in most children by ingesting tuberculous milk can be offset by vaccination with B.C.G., which seems to be capable of reducing tuberculosis morbidity and mortality by 60–80% (Francis 1949).

CONTROL

Great Britain led the world in the control of the major epizoötics during [illegible]948b), and was in the forefront o[illegible]" (Newsholme 1927, Wilson 1948). But by the time the acute epidemics had been brought under reasonable control, much of our energy, both in the human and animal field, seems to have been dissipated, and we have allowed other countries to take the lead in work on tuberculosis. However, there now seems to be a new interest in the subject and a tribute is due to Dalling and his colleagues, at the Veterinary Research Laboratory, for their work on tuberculin-testing, which forms the basis of all schemes to eradicate bovine tuberculosis. To overcome the difficulties of "non-specific" sensitisation caused by avian tubercle bacilli and other organisms, they have devised the comparative intradermal test, in which avian and mammalian tuberculin are injected simultaneously in different sites in the neck. The interpretation of the test, which is carefully defined, depends on comparison of the measurements of the two swellings. For the purpose of these tests large quantities of mammalian and avian P.P.D. (purified protein derivative) tuberculins are produced at Weybridge using the methods described by Green (1946). The great advantage of these tuberculins is that their potency can be readily standardised by chemical methods to ± 0·5%, whereas Old Tuberculin can only be standardised to ± 40% using eight guineapigs per group (Green 1946). There can be little doubt that the tuberculin-testing carried out on cattle with P.P.D. tuberculins in Great Britain is more efficient than that done in any other country. Old Tuberculin is still widely used in man, but for any extensive programme of tuberculin-testing the pure standardised product appears preferable.

---

[2] Figures for England and Wales as published by the Registrar-General. Figures for Scotland kindly supplied by Dr. P. L. McKinlay.

In 1917, when the over-all incidence of tuberculosis in the U.S.A. was probably 6–8%, eradication under the accredited herd and area plan was begun. Under this plan cattle in an area were tuberculin-tested and the reactors slaughtered. An area was claimed as "accredited" when less than 0·5% of the cattle reacted to tuberculin. The progress of the scheme is shown in figs. 3 and 4. Between 1917 and 1940, when the last county reached this status, over 200 million cattle had been tuberculin-tested. Yet this campaign in the U.S.A. often had surprisingly little support. Even such a far-sighted and penetrating observer as Krause (1919) wrote: "Nothing can be more wasteful, extravagant and unproductive of real results than the slaughter of infected cattle" and he condemned the early efforts at eradication. Drolet (1946) speaks of the value of pasteurising milk in the U.S.A. to prevent infants being infected with tubercle bacilli; he does not mention that bovine tuberculosis has been eradicated!

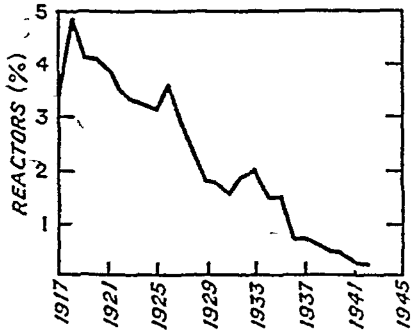

Fig. 3—Control of bovine tuberculosis in the United States of America. (The number of cattle tested between 1917 and 1942 was about 253 million. There were nearly 4 million reactors.)

In Scandinavia the position seems to have been quite different. There physicians and veterinarians have collaborated closely, and, to paraphrase Krause (1919), they have not gone to the people as scientists, physicians, experts, or officials, but as *men*. Awakening the interest of the community, they have achieved remarkable results. In Denmark in the early 1930s the incidence of tuberculosis was very similar to that in Britain. In 1932 a voluntary area eradication scheme was introduced, based on the coöperative dairies, and its progress from 1937 onwards is shown in fig. 5. Results in the Danish Islands were very good; but it became obvious that the law needed strengthening to finish the work on the mainland, and this was done in 1942 (Nielsen 1947). Under the new law the owner of a tuberculosis-free herd may insist on any farm hand being examined for tuberculosis: if the man refuses he may be discharged forthwith. The owner, for his part, must inform his cowmen if any of the cattle are found to have tuberculosis.

Denmark became virtually free from bovine tuberculosis in 1948; so it will be seen that the veterinary authorities and farming community eradicated the disease in 16 years, starting from conditions much the same as those in Great Britain in 1935. In the U.S.A., starting with a much lower percentage of reactors, it took 23 years to achieve the same result.

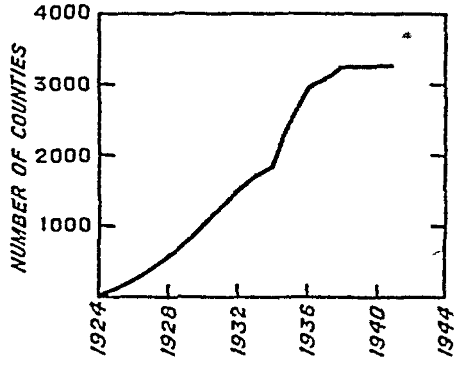

Fig. 4—Modified tuberculosis-free counties in the United States.

Magnusson (1942) describing the incidence and control of bovine tuberculosis in Sweden, mentions that partial pasteurisation was introduced in 1939 and complete pasteurisation (except for milk from tuberculin-tested herds) in 1940. When human-type infection is encountered in a herd the veterinary surgeons inform the medical board, who order an examination of the attendants, and many cases of human tuberculosis have been detected in this way. Magnusson emphasises the danger children run when they play in infected cowsheds and points out that it is not enough to exclude tuberculous animals from eradication areas, because persons with bovine phthisis can easily infect a herd.

In Great Britain the first legislative attempt to control bovine tuberculosis was the Tuberculosis Order of 1915, which was not put into force until 1925. It is largely a public-health measure, which aims at removing severely diseased animals. Grade A tuberculin-tested milk was recognised under the Milk (Special Designations) Orders, 1923, but this did little to promote a progressive increase in the number of tubercle-free herds. Accordingly the attested herds scheme was introduced in 1935, and powers to carry out area eradication were granted in the Agriculture Act of 1937. Fig. 6 shows that the rapid increase in the number of attested herds, arrested during the war, has now been resumed. There are now 1½ million cattle in attested herds, out of a population of 8–9 million, and Shetland has the distinction of being the first attested area in Great Britain. Only parts of Wales and south-west Scotland, however, contain areas on the mainland with a substantial proportion of attested herds,

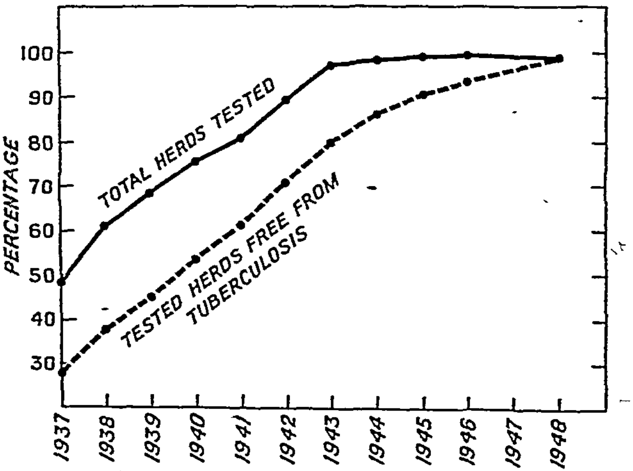

Fig. 5—Control of bovine tuberculosis in Denmark.

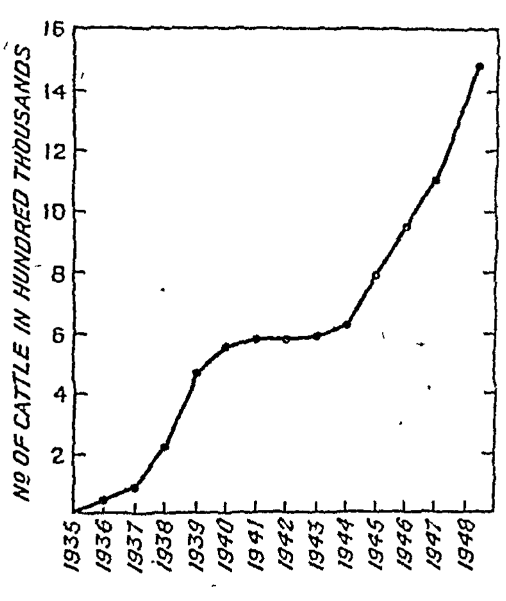

Fig. 6—Progress of the attested herds scheme in Great Britain.

and it is surprising that no steps have been taken to produce a really good area in Cornwall, Devon, Somerset, and Dorset.

Opinion differs on what is the best way of rapidly increasing the number of tubercle-free herds.[3] Ritchie and Stamp (1948) state that if 40% or more of the adult stock react they should all be sold and replaced by young stock. On the other hand, Bruford (1948) has had excellent results by using more gradual methods, and Anderson (1948) has stated that most herds became free from tuberculosis by steady replacement from their own young stock. Clearly much depends on the degree of isolation which can be provided on the farm; but in many parts of the country the need is to break the chain of infection from old to young stock on each individual farm. Success depends on the farmer and his men thoroughly understanding a few elementary principles. Once their interest is aroused this usually causes little difficulty. Arthur (1948) described how tuberculosis was eradicated by this method, within four years, from a herd in which over 80% of the adult stock were reactors.

The wider problem of how tuberculosis should be eradicated from the country as a whole was discussed at the National Veterinary Medical Association congress following a paper on the tuberculin test by Dalling (1948). Arthur (1948), outlining the complexity of the allergic state, emphasised that it was impossible to have a perfect tuberculin test. He believes that if the present test were used as the basis of a slaughter policy too many non-tuberculous animals would be slaughtered; and in any event, he said, any sudden adoption of a slaughter policy would disrupt the dairy industry and therefore the milk-supply. Many cows which react to the tuberculin test have only minimal lesions, and Arthur suggested that Government farms should be established for reactors from eradication areas. These farms would be kept under strict veterinary supervision and all the milk coming from them would be pasteurised. In Switzerland there is already an official scheme for removing infected stock from herds where eradication is taking place to other commercial herds (Balmer 1947). In Great Britain the process goes on through the markets without any supervision; yet it is probably more economical and less unsatisfactory at the present stage of progress than might be imagined.[1]

Clearly, the attested herds scheme must continue largely in its present form, though every effort must be made to simplify the tuberculin test and the administration of the scheme. In addition, the financial inducement to the farmer to eradicate tuberculosis should be reconsidered. The eradication of tuberculosis has now been taken over by the Animal Health Division of the Ministry of Agriculture as an agricultural problem, but the financial inducements still reflect the old "public health" outlook. The following bonuses are paid, per gallon, on milk from various types of herds:

Accredited	1¼d.
Accredited and attested	2¼d.
Tuberculin-tested (T.T.)	4d.
T.T. and attested	4d.
Attested but not T.T.	1d.

An attested herd is one that is taking adequate measures to protect itself from tuberculosis, whereas a T.T. herd is one that has passed a tuberculin test and reaches the accredited standard of cleanliness. It will be seen that a farmer receives a substantial bonus (4d. per gallon) for selling milk from a T.T. herd. If, however, his buildings do not reach a certain standard he gets only 1d. per gallon for carrying out the important and sometimes difficult task of eradicating tuberculosis from his herd, which is less than the 1¼d. received by another farmer who manages to obtain an ordinary accredited licence, which is sometimes notoriously easy. Sometimes, too, it is notoriously difficult to meet the sanitary requirements of the T.T. licence (Anon. 1949). These should be just the same as for an accredited licence, but some local authorities seem to impose special standards of their own. Much more consistent rulings, with much less irritation to the farmer, would be obtained if the Animal Health Division took over both the work of attestation and the issue of T.T. licences.[5]

Many farmers would eradicate tuberculosis from their herds if they could obtain the "T.T. bonus"; but they cannot obtain this because neither they nor their landlords can afford to reconstruct the cowsheds. We thus have the untenable position in which the farmers having the most unhygienic cowsheds, in which the spread of tuberculosis is most rapid, are given the least encouragement to eradicate disease. It may seem retrograde to do away with any architectural standard for cowsheds; but surely the farmer with poor buildings, who is willing to eradicate tuberculosis from his herd and constantly produces milk of good quality, is entitled to at least as much reward as his neighbour who is fortunate enough to have better buildings? In the Danish scheme of tuberculosis eradication the rewards and penalties were not linked in any way with the standard of buildings.

Eradication areas are now to be gradually established, and as this happens, and the attested herd scheme progresses, new methods of dealing with reacting animals will have to be devised. Under present economic conditions they cannot reasonably be slaughtered and some means of supervising them, perhaps on special farms, must be found. In the final stages of eradication, however, reactors will have to be slaughtered.

In the past, people interested in agriculture have felt that if pasteurisation of milk became general there would be much less support from the medical profession for the eradication of bovine tuberculosis; but it is now obvious that so long as bovine tuberculosis exists there will always be a serious risk of its communication to man by direct inhalation. Quite apart from considerations of "public health," the eradication of bovine tuberculosis will increase the efficiency of milk-production and thus improve human nutrition. There is, therefore, every reason for the medical and veterinary professions to collaborate in aiding the farming community and public to eliminate tubercle bacilli from the environment of animals and man in Great Britain.

---

[3] I have elsewhere reviewed the evidence on the value of B.C.G. in cattle (Francis 1947). It is now generally concluded that, although it produces a considerable immunity in cattle, its use is contra-indicated because the allergy produced would interfere with the tuberculin test which is the basis of the eradication policy.

[1] A proper system uld provide invaluable information on tuberculosis, as on all other diseases o precise information is so badly needed assist the campaign to eradicate bovine [illegible] (as it has in the U.S.A.) and, as pointed out recently (British Medical Journal 1949), it is the natural function of the Animal Health Division.

[5] Under the new milk regulations the Ministry of Agriculture is the body that issues licences, and the various grades of milk will be simplified.

SUMMARY

Only 18-20% of all cattle in Great Britain react to tuberculin, but all these have to be regarded as infectious. The figure of "40%," which is so widely quoted, applies only to old cows.

Once established in the human lung, the bovine tubercle bacillus is just as virulent as the human, though there is reason to think that it has greater difficulty in establishing itself in the lung, and therefore less power of spread from man to man. Scandinavian work has shown that the most serious form of bovine-type pulmonary tuberculosis in man is caused by inhaling infection from cattle, and in country districts about half of all cases of human phthisis may be caused by bovine-type infection.

The maps in fig. 2 show that in country districts in Great Britain there is an inverse relation between the incidence of bovine tuberculosis and the total mortality from human tuberculosis. Data from Denmark show that, though the proportion of tuberculin-positive persons is greater in areas where there are tubercle bacilli in the milk, tuberculous disease is not so common in such areas as it is in areas where the milk is free from bacilli.

As milk is freed from tubercle bacilli by the eradication of tuberculosis from cattle and by pasteurisation, more will have to be done to protect adolescents from infection, and increase their resistance by immunisation with B.C.G.

Of about 9 million cattle in Great Britain, some 1½ million are now in attested herds which are maintained free from tuberculosis. Area eradication of the disease is to begin next autumn.

A system of meat inspection organised by the Animal Health Division could materially assist the scheme by producing data on the incidence of tuberculosis.

The attested herds scheme is now based on the "comparative" tuberculin test in which carefully standardised mammalian and avian P.P.D. tuberculins are used. In testing human beings, however, wide use is still made of Koch's Old Tuberculin. As this cannot be accurately standardised, its replacement by purified protein derivative might be considered.

As bovine tuberculosis is eradicated the risk of cattle being infected from man will increase. People who look after cattle may need to be examined in order to prevent infection of the animals—as well as for other reasons.

Eradication of bovine tuberculosis will increase the efficiency of meat and milk production. Indeed, this may prove to be its most valuable contribution to public health and well-being.

GENERAL MEDICAL AND PHARMACEUTICAL SERVICES

AMENDING REGULATIONS

AMENDING regulations[1] have been issued by the Minister of Health under the terms of the National Health Service Act and of the amending Act, which received the Royal Assent on Dec. 16. These regulations deal with the method of filling practice vacancies, the employment of assistants, certificates to be provided without charge by practitioners, bulk prescribing for residents of schools and institutions, and restriction of advertising by contractors included in the pharmaceutical lists of executive councils. The effect of the new regulations has been set out in a circular to executive councils.

Practice vacancies.—The new regulations provide for a modified procedure, from Feb. 1, for filling "declared vacancies" (normally following the death or retirement of a doctor). It will be for the Medical Practices Committee (or the Minister on appeal) to select the doctor to fill such a vacancy, even if the doctor is already on the executive council's medical list: and all doctors whose applications are refused, including those already on the medical list, will be entitled to appeal.

The regulations also embody the understanding that where a selection has been made by the Medical Practices Committee (or on appeal the Minister) from a number of applicants to fill a vacancy created by the death or retirement of a doctor, the patients of the retiring or deceased doctor shall be transferred to the doctor selected by the Medical Practices Committee (or on appeal the Minister) unless the committee (or Minister) otherwise provide.

Employment of assistants.—At present a doctor who is refused consent by the executive council to the employment of an assistant has no right of appeal: but under the new regulations an appeal will lie to the Medical Practices Committee.

The regulations also provide for the allocation scheme to be amended so as to give a doctor who employs an assistant the right to have his list increased by a maximum of another 2100 patients if the Minister so decides. (In one case the executive council has declined to allow a doctor employing an assistant to increase his list by this maximum, even though the Medical Practices Committee had decided that there was room for that assistant in the area and had granted his application for inclusion in the medical list.) Assistants are no longer to have their names included in the medical list, or (in consequence) to have lists of patients of their own. This will be achieved by prohibiting doctors under the terms of service from employing assistants whose names are included in the medical list. The only exceptions are: (*a*) part-time assistants who are also practising separately on their own account, and who

in the latter capacity can build up lists of their own; and (*b*) assistants whose names are included in the medical list of an area on Feb. 1, when this part of the regulations takes effect.

Prescribed certificates to be issued without charge.—By the Amendment Act, a doctor may be required to issue free of charge to his National Health Service patients or their personal representatives only those certificates—being certificates reasonably required by the patients under, or for the purposes of, any enactment—which are prescribed by regulations. A schedule to the regulations gives a provisional list of such certificates, to which the General Medical Services Committee has agreed, and to which a few additions may be made. The regulations also make it clear that a practitioner is not required to issue certificates to his patients if they are receiving treatment from unqualified persons.

The provisional list comprises the following certificates:

1. To support a claim or obtain a payment either personally or by proxy, under the Family Allowances Act, 1945, the National Insurance (Industrial Injuries) Act, 1946, and the National Insurance Act, 1946.
2. To prove inability to work or incapacity for self-support for the purposes of an award by the Minister of Pensions, or to enable proxy to draw pensions, &c., under the Pensions (Navy, Army, Air Force, and Mercantile Marine) Act, 1939, the Pensions (Mercantile Marine) Act, 1942, the Naval and Marine Pay and Pensions Act, 1865, the Air Force (Constitution) Act, 1917, the Personal Injuries (Emergency Provisions) Act, 1939, and the Polish Resettlement Act, 1947.
3. To procure extra coal in cases of illness, extra milk, extra petrol, or extra rations, under the Emergency Powers (Defence) Acts, 1939–45 and other statutes.
4. To obtain permission to import foreign drugs and appliances, or to export special foods with a sick traveller or with infants, aged 2 years or less, under the Import, Export, and Customs Powers (Defence) Act, 1939.
5. To enable a patient to have his sight tested under the supplementary ophthalmic services, in accordance with the National Health Service Act, 1946.
6. To establish fitness to receive nitrous-oxide and air analgesia in childbirth (Midwives Act, 1902).
7. To secure registration of stillbirth (Births and Deaths Registration Act, 1926).
8. To enable payment to be made to another person in case of mental disability of a person entitled to payment from public funds, or to justify release of a patient from detention after absence on trial (Lunacy Act, 1890).
9. To establish unfitness for jury service (Juries Act, 1922).
10. To establish unfitness to attend for medical examination (National Service Act, 1948).
11. To support late application for reinstatement in civil employment where application has been delayed by sickness (Reinstatement in Civil Employment Act, 1944).
12. To enable a disabled person to be registered as an absent voter (Representation of the People Act, 1949).

Bulk prescribing.—Under the new regulations the requirement that a prescription on form E.C.10 may be issued only for an individual patient is relaxed in respect of a practitioner who is responsible for the treatment of not less than ten persons in a school or institution where at least twenty persons are normally resident. Under these circumstances he may now issue a bulk prescription for two or more of these residents for whom he is not receiving a dispensing capitation-fee, provided that (*a*) the prescription is limited to drugs (other than drugs to which the Dangerous Drugs Acts apply and drugs which are, or contain, fourth-schedule poisons) included in the *National Formulary* or an official supplement; and (*b*) it is endorsed by the doctor with the name and address of the school or institution and the number of residents for whose treatment the doctor is responsible.

NEW YEAR HONOURS

THE list of honours published this week contains the *names of the following members of the medical profession:*

Baron

LESLIE HADEN GUEST, M.C., M.R.C.S.
M.P. for Southwark North 1923 and 1924, and for Islington North since 1927. For political and public services.

K.C.V.O.

HAROLD KINGSTON GRAHAM-HODGSON, C.V.O., M.B. Durh., F.R.C.P.
Director, X-ray department, Middlesex Hospital, London.

K.B.E. (Civil)

THOMAS ERNEST VICTOR HURLEY, C.B., C.M.G., M.D., M.S. Melb., F.R.C.S., F.R.A.C.S.
Consulting surgeon, Royal Melbourne Hospital. For public services.

Knights Bachelor

HAROLD ESMOND ARNISON BOLDERO, D.M. Oxfd, F.R.C.P.
Dean, Middlesex Hospital medical school: registrar, Royal College of Physicians of London.

JOHN ALEXANDER CHARLES, M.D. Durh., F.R.C.P.
A deputy chief medical officer, Ministry of Health.

FRANK ARNOLD GUNASEKERA, C.B.E., M.R.C.S.
Senator, Ceylon.

WILLIAM WILLIS DALZIEL THOMSON, M.D. Belf., F.R.C.P., D.L.
Professor of medicine, Queen's University, Belfast.

THOMAS GEORGE WILSON, C.M.G., M.D. Sydney, F.R.C.O.G.
Director of obstetrics and gynæcology, University of Adelaide. For public and philanthropic services.

C.B. (Military)

Surgeon Rear-Admiral JOSEPH ARCHIBALD MAXWELL, C.V.O., O.B.E., M.B. Dubl., F.R.C.S.E., K.H.S., retd.

Major-General FRANCIS ROBERT HENRY MOLLAN, O.B.E., M.C., L.R.C.P.I., late R.A.M.C.

Air Vice-Marshal TERENCE CHARLES ST. CLESSIE MORTON, O.B.E., M.D. Edin., F.R.C.P., K.H.P.

C.M.G.

ERIC HOWARD MANLEY LUKE, M.B.
Surgeon, Wellington public hospital for over 25 years; chairman of the council, British Medical Association (New Zealand branch).

C.B.E. (Military)

Surgeon Captain THOMAS NORMAN D'ARCY, L.R.C.P.I., R.N.

Group-Captain ANDREW HARVEY, M.B. Belf., R.A.F.

C.B.E. (Civil)

Miss JANET KERR AITKEN, M.D. Lond., F.R.C.P.
Consulting physician, Elizabeth Garrett Anderson Hospital, London; member of the council, Royal College of Physicians of London.

ROBERT VIVIAN BRADLAW, M.D.S. Durh., F.R.C.S., F.D.S. R.C.S.,
Dean, faculty of dental surgery, Royal College of Surgeons of England; professor of oral pathology, University of Durham.

CLIFFORD VINEY BRAIMBRIDGE, M.V.O., M.A., M.B. Camb., F.R.C.S.E.
Senior surgical specialist, Kenya.

Miss IDA CAROLINE MANN, M.A. Oxfd, M.B., D.SC. Lond., F.R.C.S. (Mrs. Gye).
Senior surgeon, Royal London Ophthalmic (Moorfields) Hospital.

ERNEST ALEXANDER NICOLL, M.A., M.D. Camb., F.R.C.S.E.
Surgeon-in-charge, Berry Hill Hall Miners' rehabilitation centre and consulting surgeon to the Miners' Welfare Commission.

FREDERICK TAVINOR REES, M.C., B.SC. Wales, M.R.C.S.
Director-general of medical services Ministry of Pensions.

O.B.E. (Military)

Surgeon Captain ALFRED EDWARD FLANNERY, L.R.C.P.I., R.N.

O.B.E. (Civil)

OKINADE AJIBADE, L.R.C.P.E.
For public services in Nigeria.

Edgar Scott Bowes, m.r.c.s.
Chairman, Poole centre, St. John Ambulance Association.
Thomas Gregory Burnett, m.b. Manc.
Chairman, Bulawayo Hospital advisory committee, Southern Rhodesia.
Ernest Thomas Conybeare, m.d., b.sc. Lond., f.r.c.p.
Medical officer, Ministry of Health.
Panagodage Bertram Fernando, m.b. Lond., m.r.c.p.
Professor of medicine, University of Ceylon.
Robert Searson Rodney Francis, m.b.
Of Hastings, New Zealand; for services to the community in connexion with the treatment of tuberculosis.
Miss Minnie Gosden, m.b. Lond.,
Senior pathologist, Sierra Leone.
George Vert Thomson McMichael, m.b. Edin.
Medical officer of health, Paisley.
David Gwilym Morgan, b.a. Oxfd, m.r.c.s.
Administrative medical officer, United Cardiff (Teaching) Hospitals.
Arthur Harold Morley, m.b. Leeds, f.r.c.s.e.
Surgical specialist, Tanganyika.
Charles Elias Reindorf, m.d. Durh.
For public services in the Gold Coast.
Alfred Eaton Spaar, f.r.c.s.e.
Medical practitioner, Kandy.
John Hargreaves Harley Williams, m.d. Edin.
Secretary-general, National Association for the Prevention of Tuberculosis.

M.B.E. (Military)

Major Mohandirange Don Simon Jayawardena, l.r.c.p.e.
Ceylon Medical Corps (Reserve).

Public Health

Notification of Diseases of the Central Nervous System

New regulations[1] which came into operation on Jan. 1 introduce nomenclature consistent with the international standard classification of diseases, which was brought into use on the same date. They also slightly extend the scope of clinical conditions notifiable under the heads of acute encephalitis and meningococcal infection.

Acute Poliomyelitis.—The distinction formerly made between acute poliomyelitis and acute polioencephalitis was always a difficult one, and has never been adopted in other countries. On the other hand, in Sweden and some parts of the U.S.A. it has long been the practice to report cases of acute poliomyelitis (including polioencephalitis) under the sub-headings (*a*) "paralytic," which includes cases with either transient or permanent paralysis, and (*b*) "non-paralytic," which includes cases where there is no paralysis but where the diagnosis was made on clinical signs with or without examination of the cerebrospinal fluid—it is recognised that in such cases the diagnosis is often uncertain. If cases which are non-paralytic when first notified and admitted to hospital become paralysed in hospital, the ordinary procedure for correction of diagnosis by the hospital should be applied.

Acute Encephalitis.—This heading replaces the former heading "encephalitis lethargica." It is very doubtful whether true encephalitis lethargica now occurs in this country, and under the new sub-heading "infective encephalitis" can be included cases of all forms of encephalitis, some of obscure ætiology, which are presumed to be of microbic or viral origin. The sub-heading "post-infectious" covers the forms of encephalitis occasionally following, or associated with, certain well-defined infections—e.g., chickenpox, measles, mumps, and vaccinia.

Meningococcal Infection.—This heading includes, as well as meningococcal meningitis (formerly notified as cerebrospinal fever), illness due to fulminant and other forms of meningococcal infection[2] without an initial meningitis.

---

[2] Banks, H. S. *Lancet*, 1948, ii, 635, 677.

Typhoid in a Liner

From the liner s.s. *Moollan* some 45 members of the crew are now in hospital; and in 30 of these the diagnosis of typhoid fever has been confirmed. Stool specimens have demonstrated 5 ambulant excretors. Among the passengers there have been 8 cases—1 each from Northern Ireland, Scotland, Lowestoft, Oldham, Shrewsbury, Sunderland, Twickenham, and Wandsworth. The dates of onset, where known, suggest that the source of infection arose during the last three weeks of the voyage and persisted until the vessel docked in the Port of London on Dec. 15. Chloramphenicol is proving of great value in treatment.

Poliomyelitis

In the week ended Dec. 24, notifications in England and Wales were: poliomyelitis 71 (87), polioencephalitis 10 (6). Notifications in the previous week are shown in parentheses.

The Third Quarter

ENGLAND AND WALES

Provisional figures published in the Registrar-General's quarterly return[1] show that the stillbirth and the infant-mortality rates for the September quarter, 1949, were the lowest ever recorded for any quarter.

Births.—The number of live births registered was 183,278, giving a rate of 16·6 per 1000 total population, which may be compared with 17·5, 20·0, and 19·8 in the third quarters of 1948, 1947, and 1946 respectively. The number of illegitimate births, included in the total, was 9248, or 5·0% of the total births registered, compared with 10,186 or 5·3%, in the corresponding quarter of 1948. There were 4104 stillbirths registered during the quarter, giving a rate of 21·9 per 1000 live and still births, compared with 4447 and the previous lowest rate of 22·7 in the same period a year ago.

Deaths.—101,207 deaths were registered during the quarter, giving a rate of 9·2 per 1000 total population. This compares with 101,545 deaths and a rate of 9·3 for the corresponding quarter of 1948, and an average death-rate of 9·3 for the third quarters of the five years 1943–47. Deaths from acute poliomyelitis and polioencephalitis (provisional total, excluding non-civilians) numbered 250, compared with 60, 83, 27, and 28 in the four preceding quarters.

Deaths of children under one year of age numbered 4883, representing an infant-mortality rate of 26 per 1000 related live births, compared with 5514 deaths and a rate of 28 per 1000 in the same period last year, which was the previous lowest rate recorded for any quarter. The diarrhœa death-rate for children under two years was 2·6 per 1000 births.

Natural Increase.—The births registered exceeded the deaths by 82,071, the corresponding increases for the third quarters of 1946, 1947, and 1948 being 112,642, 119,409, and 90,313.

Survey of Sickness.—Out of 3509 men interviewed, 2186 reported having had some illness or injury in May and there were 1478 consultations with doctors; out of 4323 women interviewed, 3167 reported having had some illness or injury in the same month and there were 1856 consultations with doctors. Illness or injury of some kind during a month in the period April, May, June was reported by 68·1% of all persons interviewed; the average incapacity was 0·90 of a day per month. Among housewives, 76·5% reported having had some illness or injury during a month.

SCOTLAND

In Scotland[2] the death-rate was the lowest ever recorded; the death-rate from tuberculosis was lower, and for both respiratory and non-respiratory forms the rates were better than the average. The maternal-mortality and the infant-mortality rates were the lowest ever recorded in Scotland.

Births.—Live births numbered 23,322, giving a rate of 17·9 per 1000 population, compared with 24,389 and a rate of 18·7 in the corresponding quarter of 1948. The proportion of illegitimate births—5·5%—was 0·2 below that for the third quarter of 1948, and 1·4 below the average. The number of stillbirths registered during the quarter was 641—equivalent to a rate of 27 per 1000 total births.

---

[1] The Registrar-General's Quarterly Return of Births, Deaths, and Marriages: Quarter ended Sept. 30, 1949. H.M. Stationery Office. Pp. 29. 1s.

[2] Quarterly Return of the Registrar-General, Scotland: Births, Deaths, and Marriages registered in the Quarter ended Sept. 30, 1949. H.M. Stationery Office. Pp. 28. 1s.

Deaths.—These numbered 13,118, equalling a rate of 10·1 per 1000 population, which is 0·4 lower than in the third quarter of 1948 and 0·4 below the five-year average. The death-rate from all forms of tuberculosis was 59 per 100,000, that from respiratory tuberculosis being 51 and that from other forms 8 per 100,000. The rate for all forms was 7 below that in the corresponding quarter of 1948 and 9 below the average. The respiratory-tuberculosis death-rate was 8 below that for the third quarter of 1948 and 4 below the average. The maternal-mortality rate was 0·9 per 1000 live births—1·2 below the five-year average. The infant-mortality rate was 35 per 1000 related live births, which was 5 lower than that for the corresponding quarter of 1948 and 14 lower than the five-year average.

Towards Cleaner Food

An illustrated booklet[1] of 49 quarto pages, prepared for internal use in their canteens by Messrs. Marks and Spencer, includes a historical sketch, the legislation relating to hygienic food-handling, a simple statement of the significance of germs, and precise rules for the practice of hygiene as it affects persons, foodstuffs, service, equipment, premises, vermin control, and storage. Apart from the excellence of its production and the sound complete advice upon all the important aspects of food-handling in catering establishments, this little work is an encouraging sign of the increasing realisation of the importance of clean food to public health.

London's Health Service

With the start of the National Health Service on July 5, 1948, the London County Council lost charge of the municipal hospital service which it had diligently built up since 1930. In his report for 1948,[2] Sir Allen Daley, the county medical officer of health, recalls that the service comprised 98 hospitals with a pre-war bed complement of 70,120 and a staff of about 32,000. The council's hospitals were transferred to one or other of the four Metropolitan regional hospital boards, except that the Hammersmith Hospital (to which is attached the Postgraduate Medical School of London) was transferred to the board of governors of the Hammersmith, West London, and St. Mark's group of hospitals; the Maudsley Hospital (to which is attached the Institute of Psychiatry) to the Bethlem Royal and Maudsley Hospitals board of governors; the St. Pancras Hospital to the University College Hospital board; and the North Western Hospital to the Royal Free Hospital board.

If in some respects the load of the council's responsibility has been eased, in others it has been increased. For example, on the appointed day the control of maternity and child-welfare centres was transferred to the L.C.C. from the various borough councils. Few of the transferred buildings were freehold or were even held on long leases, and the premises were mainly improvised. Of the specially designed centres, many fulfilled functions that became the responsibility of the council on the one hand and of one of the regional boards on the other, while in a few instances the borough council still retained a residual interest in the building. "These buildings became subject to 'apportionment' between the various claimants, and negotiations to solve the complex questions involved in their future ownership and administration were still proceeding at the end of the year." As a long-term policy there are to be comprehensive health centres in each of the 162 "health service" areas of the county (and compared with other authorities, the L.C.C. can count itself lucky to have one of them actually under construction).

In the latter half of 1948 the equivalent of twenty full-time dentists resigned from the school dental service, and 27 out of 73 surgeries had to be closed or partly closed.

Each year the report is to include a detailed survey of one section of the council's work; and the present report reviews the origin and operation of the domiciliary midwifery service.

A Running Commentary by Peripatetic Correspondents

ALL these articles on the adrenal cortical hormones, and the less recent ones on the Rh factor, have convinced me that the average man cannot expect to understand such things without either (*a*) taking a month's holiday and doing a few hours' rhesus research and cortical questing between long country walks, or (*b*) turning into a gibbering lunatic bereft of the power of normal speech and restful sleep. The authors of the articles aforesaid could help by dressing their ideas and facts in some of those funny little coloured symbols, showing $3^1/_2$ labouring men or $4^3/_4$ bales of cotton, which grace the modern geographical primers. When considering A.C.T.H., L.A.P., O.A., R.H.D., O.H.M.S., D.O.C.A., N.A.D., S.M.R., and O.G.P.U., it would be nice for the reader to know just who was on whose side. For instance, all those *for* rheumatoid arthritis (or hæmolytic anæmia, or what you will) could be printed in pink, and all those agin it in bold green, Doubtful Depressors (the villains) in a pale yellow, and Probable Stimulators in bright jazz patterns. All references to members of a control series could be printed in Gothic type, and significant results be stamped in gold with the values for t and χ^2 etched beneath in vermilion filigree. The article should end with a jolly little verse embodying all the main points in the argument; music to which the said verse can be sung in the bath or used as a college war-cry; a summary of the verse; and a frank confession of all the author's little peccadilloes, bees in bonnet, and lost causes, and any illuminating intimate peculiarities, such as whether he wears long or short pants.

* * *

Doctors, I know, must not be witch doctors; but as a patient I feel they might do more to preserve us from things that go bump in the night. I write as a man in the early forties with an artificial pneumothorax now almost in its dotage—it is more than 11 years old.

My A.P. went through the normal progression of refills, division of adhesions, more refills, occasional fluid, more refills—about 200 refills, I estimate, before the fluid finally fibrosed and the lung (who shall blame it?) decided that was that and sat down. All the time I have been happy, healthy, and hard-working, and I still am. I have no complaints, only gratitude to a grand profession.

But—about those things that go bump in the night. If all T.B. specialists had experienced an A.P., which heaven forfend, they would think more of warning the patient of what to expect. An artificial pneumothorax is followed by the most alarming explosions, crashes, heavings, lurches, twangings, bumps, and flutterings; and most of them happen in the night. Medically they do not mean a thing. To the patient they can cause panic and a sense of impending doom.

Some three months after my A.P. induction, adhesions were divided. Next morning a gobbet of sputum bubbled up most satisfactorily and I have never been troubled in that way since. Medically speaking, the surgeon had done a perfect job. But two nights later, as I was toppling over the edge of sleep, an atom bomb exploded in my chest. There was no pain—just sensation. But what a sensation! My little world had blown up, and I, of course, was about to die. In seconds my mind raced through all the possibilities and all the impossibilities as well. Panic seized me. My breathing jangled, my palms sweated, my limbs went limp, and I only just managed to ring for the night nurse. She scurried along the corridor, the doctor panted up the stairs. And of course there was nothing wrong with me at all. An adhesion had slipped. Immediately the doctor told me what had happened I stopped dying. Instead, I felt rather a fool. Two nights later another bomb exploded and I laughed at it.

Why on earth did not the doctor warn me? If he had told me that such a thing might happen, and that if it happened it didn't matter a hoot, I would have been saved a temporary but embarrassing demise.

Six months later, when I left the sanatorium to have a few weeks at the seaside before returning to work, I had another gefuffle. (I have always called these terrifying but harmless sensations gefuffles, and I am

beginning to think that the word is needed in the medical lexicon.) This gefuffle took the form of a sudden tightening of the breathing, followed by an unnatural freedom and loss of the respiratory rhythm. As I was no longer surrounded by the comfort of a sanatorium I worked that one out for myself. I guessed it was plain wind, first pressing on the diaphragm and then going away, but creating a sensation which would induce panic in the uninitiated. Doctors may find it difficult to believe that even intelligent patients think that their lungs are as deep in the front as they are at the back. Any sensation above the navel is at once related to the lungs. That does not matter to a man in health. He passes it off with a shrug or a drink. But one who has had an A.P. thinks straight away: "It's me chest!"

What a deal of apprehension the patient could be saved if doctors would come clean and tell him what is liable to happen. This is particularly important in a sanatorium. There, surrounded by medical aid and ability, the patient feels secure. He is in the womb of science. Then, after a few months, he is delivered into a harsh world he has almost forgotten. He may be medically fit, but his mind has undergone a subtle change. He no longer takes his body for granted. He has lost trust in the ability of his involuntary functions to work smoothly and efficiently. He regards every deviation from the normal with grave suspicion. True, there are aftercare lectures. Don't we remember them! "Never stand when you can sit. Never sit when you can lie down. Don't get tired. Don't lie in the sun. Rest . . . rest . . . rest." But we are never told what to do when something shifts and feels like the clutch of doom. We find out; but would it not be better to tell us? A funny feeling within the aseptic walls of a sanatorium is one thing; a funny feeling in the middle of Piccadilly is quite another. All this, and claustrophobia too, is the burden of the rehabilitated tuberculous patient.

Doctor, there is an ordinary bloke with ordinary fears behind that orderly collapse. Tell him everything is all right. But at the same time warn him about the gefuffles that will seem so much but mean so little.

* * *

Christmas Eve on the marshes was mild, misty, and windless. The open sheets of water were covered with hundreds of teal and wigeon, a few mallard, coots, black-tailed godwits, and redshanks, and a solitary dabchick. I was standing half-hidden by a tall clump of reeds, when a sudden startling "whee-ee-ee-eesh," like a shell splitting the air, made me look up. A compact bunch of sixteen ducks whizzed over me and settled on the water behind the reeds without having seen me; so I made a long and difficult detour through reed-beds and flooded ditches to get a view of them from behind some dead willows. Alas, they were too wild. After my hard work they saw me and took off in alarm and sped swiftly out to sea, whereas teal, wigeon, et al. continued their peaceful occupation of the water unaffrighted. But I had just time to note that there were five drakes, each with a dark head carried high on a long white neck, and eleven ducks somewhat resembling female mallard. Before I came away, however, another drake arrived with two ducks, again whooshing overhead like a shell from a gun. That's pintail, that was.

PERDITA

How came a golden retriever bitch
To be all by herself on a bus?
Since nobody owned her,
We quietly boned her.
That's how she came to us.
The County Police took down the facts
At enormous and tedious length.
Since no-one has claimed her,
We've formally named her
And taken her on the strength.
But why such a comely and shy young bitch
Should be travelling solo thus,
Is, it must be admitted, a question which
Is one too many for us.

Letters to the Editor

THE FIRST MEDICAL EXAMINATION

SIR,—The letter from C. C. Hentschel in your issue of Dec. 17 calls for some reply from the schools and indeed from the general public.

As possible patients we are deeply concerned that the doctors who attend on us shall not be mere mechanics or technicians, but shall be possessors of a broad and humane outlook. We believe this outlook is an essential constituent of the healer's art, and we know that it is in the best traditions of the medical profession, where the doctor has occupied the rôle of wise counsellor and friend, not simply that of pill-prescriber or sawbones. As educationists we play our part in seeing that future doctors shall possess these qualities. We should like to stress the unique opportunity enjoyed by the boy who remains at school up to the age of 18 to take his first medical examination. Once he has left school for a medical school he will be a specialist surrounded by specialists, and will in any case not be afforded time for any education in the humanities. But at school he has direct contact with men and boys devoted to a wide range of humane studies. He lives with them, plays games with them, and does some of his serious study with them. If we "allowed him to concentrate" on physics, chemistry, and biology from the age of 16, we should not be serving the interests either of the medical profession or of the community at large.

The thing which accounts for the high proportion of failures in the London 1st M.B., and which does urgently need altering for the better, and which can, with the assistance of C. C. Hentschel, easily *be* altered, is the syllabus and exemption rules for the examination itself, particularly in biology.

We have an average of about 8 boys annually in our Upper Sixth biology class. Some will be intending to go to Oxford or Cambridge, some to other universities, some to London. Most other universities will grant exemption from 1st M.B. on a General Certificate of Education at "A" level in physics, chemistry, and biology (the old H.S.C.), given by any examination syndicate. London will not accept other syndicates' biology. For London the candidate must either offer both zoology and botany (which obliges him to go much further in botany than is valuable to him, and is a frequent source of frustration and discouragement, if not failure); or he must abandon the Certificate (and with it the possibility of being awarded a State scholarship) and take London 1st M.B. externally.

The biology syllabus for this last examination is quite out of sympathy with modern ideas and is so designed that it does not coincide with that for any other biological or 1st M.B. examination. It is this, rather than lack of experienced teachers, that handicaps schools in preparing external candidates by enforcing an unnecessary variety of teaching in the biology sixth. Among other things we would particularise as follows:

1. A mass of detailed embryology is included, involving about 3 or 4 weeks' work and additional to that shared with other syllabuses.
2. There is an emphasis on the more formal comparative anatomy and physiology and a complete absence of ecology and natural history. (Contrast these with the syllabus of the Oxford and Cambridge Joint Committee, 1944, which (pp. 3–4) "has reached the conclusion that the biological sections of the preliminary Medical Examinations should be confined to testing such biological work as is properly included in a general scientific education at school" and (p. 5) believes "that individual study of natural history provides the finest training of this kind" (i.e., scientific judgment).)
3. No human and economic biology is specified.
4. The published syllabus is vague on many points, which makes it difficult for the school teacher to give a boy reasonable help and guidance, and may give the internal student

number of stillbirths registered during the quarter was 641—equivalent to a rate of 27 per 1000 total births.

Deaths.—These numbered 13,118, equalling a rate of 10·1 per 1000 population, which is 0·4 lower than in the third quarter of 1948 and 0·4 below the five-year average. The death-rate from all forms of tuberculosis was 59 per 100,000, that from respiratory tuberculosis being 51 and that from other forms 8 per 100,000. The rate for all forms was 7 below that in the corresponding quarter of 1948 and 9 below the average. The respiratory-tuberculosis death-rate was 8 below that for the third quarter of 1948 and 4 below the average. The maternal-mortality rate was 0·9 per 1000 live births—1·2 below the five-year average. The infant-mortality rate was 35 per 1000 related live births, which was 5 lower than that for the corresponding quarter of 1948 and 14 lower than the five-year average.

Towards Cleaner Food

An illustrated booklet [1] of 40 quarto pages, prepared for internal use in their canteens by Messrs. Marks and Spencer, includes a historical sketch, the legislation relating to hygienic food-handling, a simple statement of the significance of germs, and precise rules for the practice of hygiene as it affects persons, foodstuffs, service, equipment, premises, vermin control, and storage. Apart from the excellence of its production and the sound complete advice upon all the important aspects of food-handling in catering establishments, this little work is an encouraging sign of the increasing realisation of the importance of clean food to public health.

London's Health Service

With the start of the National Health Service on July 5, 1948, the London County Council lost charge of the municipal hospital service which it had diligently built up since 1930. In his report for 1948,[2] Sir Allen Daley, the county medical officer of health, recalls that the service comprised 98 hospitals with a pre-war bed complement of 70,120 and a staff of about 32,000. The council's hospitals were transferred to one or other of the four Metropolitan regional hospital boards, except that the Hammersmith Hospital (to which is attached the Postgraduate Medical School of London) was transferred to the board of governors of the Hammersmith, West London, and St. Mark's group of hospitals; the Maudsley Hospital (to which is attached the Institute of Psychiatry) to the Bethlem Royal and Maudsley Hospitals board of governors; the St. Pancras Hospital to the University College Hospital board; and the North Western Hospital to the Royal Free Hospital board.

If in some respects the load of the council's responsibility has been eased, in others it has been increased. For example, on the appointed day the control of maternity and child-welfare centres was transferred to the L.C.C. from the various borough councils. Few of the transferred buildings were freehold or were even held on long leases, and the premises were mainly improvised. Of the specially designed centres, many fulfilled functions that became the responsibility of the council on the one hand and of one of the regional boards on the other, while in a few instances the borough council still retained a residual interest in the building. "These buildings became subject to 'apportionment' between the various claimants, and negotiations to solve the complex questions involved in their future ownership and administration were still proceeding at the end of the year." As a long-term policy there are to be comprehensive health centres in each of the 162 "health service" areas of the county (and compared with other authorities the L.C.C. can count itself lucky to have one of them actually under construction).

In the latter half of 1948 the equivalent of twenty full-time dentists resigned from the school dental service, and 27 out of 73 surgeries had to be closed or partly closed.

Each year the report is to include a detailed survey of one section of the council's work; and the present report reviews the origin and operation of the domiciliary midwifery service.

It would be unrealistic to assume, while the economic "crisis" and the shortage of nursing staff persist, that any large increase in the total number of beds available for the treatment of tuberculosis is possible, except through the diversion of general-hospital beds to this purpose. There would seem therefore to be a strong case for the closest possible collaboration between the sanatorium and the clinic physician, possibly on the lines indicated by Dr. Climie and Dr. Roe (Dec. 24), though I see no absolute need for the sanatorium physician to surrender the control of beds used in this way if collaboration is effective. Certainly there is a good case against such action.

The quotation given in this letter seems to suggest that any future decline in the death-rate might be accompanied by the closure, or diversion to other purposes, of a comparable number of beds. I think we shall be well advised to see that this does not happen before the desired ratio of $2^{1}/_{2}$–3 beds per death is achieved.

The National Sanatorium,
Benenden, Kent.

T. W. Lloyd
Chief Medical Officer.

ACADEMIC SALARIES

Sir,—The progress of medical research during the present century has provided ever-increasing evidence of the contribution which can be made by the non-medically qualified scientist. Today, not only biochemists but also pathologists, bacteriologists, pharmacologists, physiologists, and even anatomists not infrequently enter their chosen subject by way of an honours degree in one of the physical or biological sciences rather than by way of a medical qualification. An adequate appreciation of much modern clinical practice demands a "scientific" outlook on the part of the clinician, and it is therefore not surprising that the most progressive medical schools contain a considerable proportion of non-medically qualified preclinical teachers.

The development of the medical sciences is therefore in grave danger of being checked by the recent tendency of hospitals, universities, and research institutions to offer research and preclinical teaching appointments at two salary scales often differing by as much as 30% according to whether the successful applicant has a medical qualification or not. In these appointments there is no suggestion that a suitably qualified applicant who does not possess a medical degree is not fully competent to occupy the post. The inevitable consequence of this policy, if it becomes general, must be to deter young men from entering the medical sciences by any route other than that provided by a medical course and to encourage older men to sacrifice potentially productive years in acquiring a medical qualification.

The protest of Dr. Harris and Dr. Bull (Dec. 17, p. 1150) should be seen in relation to this wider problem. One cannot but admire the firm refusal of Cambridge University to surrender an important academic principle to expediency, and its insistence that in the absence of any possibility of a general increase of university salaries to the proposed medical level, the medical scales should be applied only to those with definite clinical responsibility. A valid grievance does, however, remain; it is most unfortunate that wide discrepancies have appeared in the policies of different universities in this matter of medical-school salaries. It is to be hoped that these important issues, vital for the future of medical research and teaching in this country, will be considered without delay at the highest levels.

Oxford.

V. P. Whittaker.

INTRAVENOUS CANNULA

Sir,—Mr. Hughes's clear instructions (Dec. 17, p. 1156) on the elementary principles involved in intravenous therapy should prove of value to the student dresser or to the inexperienced houseman. His diagram of the no. 20 s.w.g. needle should give a clear picture of it to those not acquainted with this standard type of needle.

His criticism of Ellis's cannula-needle is not so clear. Just as an experienced anæsthetist could no doubt render a patient unconscious with a rag and a bottle of chloroform, so the angler could catch a fish with a piece of string and a bent pin. Both the anæsthetist and the angler, however, appear to have benefited from the improvements in their respective equipments. The expert angler may not catch more fish with a good rod, but the occupation is pleasanter.

The needle-cannula devised by Dr. Ellis possesses advantages, enumerated in his article of Oct. 15, over other instruments for intravenous therapy. It may be that if Mr. Hughes were an angler instead of, or as well as, a surgeon, he would prefer the string and pin technique.

Manual dexterity should not impede technical progress, and in some people manual dexterity does tend to become rather a passion.

"The ruling passion, be it what it will,
The ruling passion conquers reason still."

London, W.1.

J. Douglas Robertson.

Sir,—The invention or production of new surgical appliances is not for the purpose, as suggested by Mr. Hughes, of dispensing with technical skill, but rather to augment and direct such skill to the highest possible degree. The technique outlined by Mr. Hughes is, with personal modifications, that adopted by all who have much practice in intravenous therapy. There are however, some points which are open to criticism.

Mr. Hughes states that the cubital veins are only used in exceptional circumstances; the forearm veins are nearly always accessible. Naturally one avoids the cubital veins if possible, unless a rapid transfusion of a small amount of blood or other fluid, is being given. In women, young children, and obese men, the forearm veins are not so frequently accessible as is suggested by Mr. Hughes. In such patients one can often find a leg vein which is suitable.

Many operators find that as much dexterity can be acquired without the use of a syringe attached to the needle. This is my experience.

It is not always possible to "feel" the needle point through the vein wall. Many vein walls are extremely thin and offer less resistance to the needle than the surrounding fascia.

It may be that Mr. Hughes can invariably set up a transfusion in a few minutes. I have seen the most experienced surgeons fail to do so after a much longer time. Indeed venous spasm or unsuitable veins may necessitate cutting down.

Two small points in technique may be mentioned. Firstly warming the limb, and secondly light tapping over a vein will often result in dilation of the latter.

The advantages of the cannula-needle, as described, are as follows:

1. The incidence of post-transfusion venous thrombosis is less, because the blunt cannula does less harm to the vascular endothelium than a sharp needle point.
2. Entry into a tortuous vein is possible. It is impossible to thread a needle along such a vein, which may be the only one available.
3. If the cannula becomes blocked, another can be inserted through the external needle remaining in the vein. This saves the patient the unpleasantness of another vein puncture.

Lastly I would mention that an intermittent intravenous drip is not always due to faulty technique, an advantage over the external. For example, there is no indication of the scope of the work required in animal histology, or in animal physiology, or in plant anatomy. (Contrast this with the Cambridge Joint Syllabus.)

The 1st M.B. syllabus should everywhere be determined by the course that is most desirable on general educational grounds. It is to be hoped that London, usually in the forefront, will not on this occasion lag behind the other universities.

PEPTIC ULCER

SIR,—A ten-year follow-up of patients with peptic ulcer is of great interest to physicians, and important conclusions are reached by Dr. Martin and Dr. Lewis in their paper of Dec. 17. Hence it is particularly necessary to examine their material to see that it is capable of sustaining the conclusions.

According to Martin and Lewis, "medical treatment did not appear to have influenced the natural course of the disease." It would be supposed, therefore, that they had observed groups of patients comparable in all respects other than that of treatment. But this is not so. On the contrary, "apart from essential surgery dictated by perforation, the majority of patients were treated medically." Medical treatment is not defined and we are not told what proportion did not have a course of medical treatment. It appears later (in their table v) that all the patients used for the assessment of medical treatment had medical treatment with or without the additional suture of a perforation. Thus it is at least arguable that the initial medical treatment in hospital was partly responsible for the recovery of the 44% of patients with gastric ulcer and of the 32·5% of patients with duodenal ulcer who, surviving to follow-up, ceased to have symptoms.

Alternatively, Martin and Lewis may mean that *continued medical treatment at home* did not influence the natural course of the disease. The evidence they cite is that while 94% of the gastric and duodenal ulcers which were active at follow-up were in patients who had taken a regular or an occasional gastric regimen, 55% of the ulcers which were inactive were in patients who had abandoned treatment. If by the "abandonment of treatment" we are to understand that they did not treat themselves at all after leaving hospital, it would appear that medical treatment might even be harmful—though before reaching a conclusion one would need to know something about the comparability of the ulcers in the two groups on discharge from hospital. But if treatment was abandoned later, it is essential to know the time relations of the cessation of treatment and of activity. Martin and Lewis recognise that it is possible "that the continued activity of both gastric and duodenal ulcers favoured perseverance with the ulcer regimen and that inactivity encouraged abandonment of treatment." Indeed, as they comment, "this is only human nature." How then can it be concluded that "medical treatment did not appear to have influenced the natural course of the disease" when it can as reasonably be deduced that the natural course of the disease influenced the treatment?

Passing on to consider the "criteria of chronicity," Martin and Lewis note that "no active gastric or duodenal cases had, at follow-up, a duration of activity of less than five or ten years"—an observation which is not surprising when it is remembered that, by definition, "active ulcers" were active at the beginning and end of a ten-year period of follow-up. It is, therefore, hardly relevant to the question of when a gastrectomy ought to be performed. In the same context, the assertion that "if activity is prolonged to . . . beyond fifteen years an ulcer almost certainly will not heal" is contradicted by their own figures. According to table IX there must have been some 18 to 23 surviving patients with a history of more than fifteen years' symptoms on admission to hospital, yet of these 6 to 11 became inactive. In fact, however, the prognosis cannot be as good as this, since the large number of deaths from peptic ulcer (75 out of 356) should also be taken into consideration.

Finally, to what extent were the patients admitted to hospital with gastric and duodenal ulcers representative of all the patients with ulcer in the district? This must be known before a comparison can be made between the chances of bleeding, &c., in gastric and in duodenal ulcers. The fact that the gastric-duodenal ratio in the series was 2·3 : 1, against the more usual figure for the South of England of 1 : 3 (or at the most 1 : 1), suggests that the common practice of admitting uncomplicated gastric ulcers more readily than uncomplicated duodenal ulcers may have been in operation. If this were so, it must have biased the results.

Gastroenterological Department,
Central Middlesex Hospital.
RICHARD DOLL.

CONTROL OF TUBERCULOSIS

SIR,—I find myself in full agreement with those chest physicians who hold that they should have some control in the treatment of their patients while in sanatoria. The period spent in the sanatorium is only a small portion of the time required to arrest a case of pulmonary tuberculosis; but it is in the sanatorium that the decision is made as to how the patient should be treated —e.g., by artificial pneumothorax or other form of collapse therapy. It appears reasonable that the chest physician in charge of the case both before and after sanatorium should be consulted before this decision is made, and this is best done by enabling him to attend the sanatorium regularly.

A scheme somewhat similar to that suggested by Dr. Climie and Dr. Roe (Dec. 24) was in operation at Ware Park Sanatorium under the Hertfordshire tuberculosis scheme before July, 1948, and was found to work satisfactorily. A "round" of the bed-patients was made each week by the medical superintendent (who was also the chief tuberculosis officer), accompanied by the chest physicians and the resident staff. The decision about treatment was reached before or during these rounds; and when opinions differed, the last word was with the chest physician under whose care the patient was admitted.

Ware Park Sanatorium, Ware, Herts.
A. P. FORD.

SIR,—Dr. Trenchard[1] has suggested that common agreement has been reached on the need for $2^{1}/_{2}$–3 beds per annual death from tuberculosis. The development of this estimate in the U.S.A., first put forward only seven years ago, was sketched in a recent editorial[2] the theme of which was that, with the object of eradicating tuberculosis, the figure should be raised to 10 beds per annual death. The following extract from a report by the chief medical officer of the Ministry of Health[3] is therefore of interest:

> "Before the war there was approximately one bed for every death from all forms of tuberculosis and it was estimated that 4 beds for every 5 deaths should meet the needs of the country. . . . If . . . tuberculosis mortality continues its downward trend, it is reasonable to expect that the existing total of some 30,000 beds, if fully staffed, should suffice for the next few years and that thereafter the requirement will diminish."

I have not been able to find any more recent statement by the chief medical officer suggesting a change of opinion

2. Bogen, E. *Amer. Rev. Tuberc.* 1949, 59, 707.
3. Ministry of Health: On the State of the Public Health during Six Years of War. H.M. Stationery Office, 1946; p. 62.

this matter, and it therefore seems possible that the ficial estimate of our needs is still 1 or 1·2 beds per nnual death, and that the North West Metropolitan egion has 0·05 beds more than it has any right to xpect!

It would be unrealistic to assume, while the economic crisis" and the shortage of nursing staff persist, that ny large increase in the total number of beds available or the treatment of tuberculosis is possible, except hrough the diversion of general-hospital beds to this urpose. There would seem therefore to be a strong ase for the closest possible collaboration between the anatorium and the clinic physician, possibly on the ines indicated by Dr. Climie and Dr. Roe (Dec. 24), hough I see no absolute need for the sanatorium hysician to surrender the control of beds used in this vay if collaboration is effective. Certainly there is a good ase against such action.

The quotation given in this letter seems to suggest hat any future decline in the death-rate might be ccompanied by the closure, or diversion to other purposes, of a comparable number of beds. I think we hall be well advised to see that this does not happen before the desired ratio of 2½–3 beds per death is chieved.

The National Sanatorium,
Benenden, Kent.

T. W. LLOYD
Chief Medical Officer.

ACADEMIC SALARIES

SIR,—The progress of medical research during the present century has provided ever-increasing evidence of the contribution which can be made by the non-medically qualified scientist. Today, not only biochemists but also pathologists, bacteriologists, pharmacologists, physiologists, and even anatomists not infrequently enter their chosen subject by way of an honours degree in one of the physical or biological sciences rather than by way of a medical qualification. An adequate appreciation of much modern clinical practice demands a "scientific" outlook on the part of the clinician, and it is therefore not surprising that the most progressive medical schools contain a considerable proportion of non-medically qualified preclinical teachers.

The development of the medical sciences is therefore in grave danger of being checked by the recent tendency of hospitals, universities, and research institutions to offer research and preclinical teaching appointments at two salary scales often differing by as much as 30% according to whether the successful applicant has a medical qualification or not. In these appointments there is no suggestion that a suitably qualified applicant who does not possess a medical degree is not fully competent to occupy the post. The inevitable consequence of this policy, if it becomes general, must be to deter young men from entering the medical sciences by any route other than that provided by a medical course and to encourage older men to sacrifice potentially productive years in acquiring a medical qualification.

The protest of Dr. Harris and Dr. Bull (Dec. 17, p. 1150) should be seen in relation to this wider problem. One cannot but admire the firm refusal of Cambridge University to surrender an important academic principle to expediency, and its insistence that in the absence of any possibility of a general increase of university salaries to the proposed medical level, the medical scales should be applied only to those with definite clinical responsibility. A valid grievance does, however, remain: it is most unfortunate that wide discrepancies have appeared in the policies of different universities in this matter of medical-school salaries. It is to be hoped that these important issues, vital for the future of medical research and teaching in this country, will be considered without delay at the highest levels.

Oxford.

V. P. WHITTAKER.

INTRAVENOUS CANNULA

SIR,—Mr. Hughes's clear instructions (Dec. 17, p. 1156) on the elementary principles involved in intravenous therapy should prove of value to the student dresser or to the inexperienced houseman. His diagram of the no. 20 S.W.G. needle should give a clear picture of it to those not acquainted with this standard type of needle.

His criticism of Ellis's cannula-needle is not so clear. Just as an experienced anæsthetist could no doubt render a patient unconscious with a rag and a bottle of chloroform, so the angler could catch a fish with a piece of string and a bent pin. Both the anæsthetist and the angler, however, appear to have benefited from the improvements in their respective equipments. The expert angler may not catch more fish with a good rod, but the occupation is pleasanter.

The needle-cannula devised by Dr. Ellis possesses advantages, enumerated in his article of Oct. 15, over other instruments for intravenous therapy. It may be that if Mr. Hughes were an angler instead of, or as well as, a surgeon, he would prefer the string and pin technique.

Manual dexterity should not impede technical progress, and in some people manual dexterity does tend to become rather a passion.

> "The ruling passion, be it what it will,
> The ruling passion conquers reason still."

London, W.1.

J. DOUGLAS ROBERTSON.

SIR,—The invention or production of new surgical appliances is not for the purpose, as suggested by Mr. Hughes, of dispensing with technical skill, but rather to augment and direct such skill to the highest possible degree. The technique outlined by Mr. Hughes is, with personal modifications, that adopted by all who have much practice in intravenous therapy. There are however, some points which are open to criticism.

Mr. Hughes states that the cubital veins are only used in exceptional circumstances: the forearm veins are nearly always accessible. Naturally one avoids the cubital veins if possible, unless a rapid transfusion of a small amount of blood or other fluid, is being given. In women, young children, and obese men, the forearm veins are not so frequently accessible as is suggested by Mr. Hughes. In such patients one can often find a leg vein which is suitable.

Many operators find that as much dexterity can be acquired without the use of a syringe attached to the needle. This is my experience.

It is not always possible to "feel" the needle point through the vein wall. Many vein walls are extremely thin and offer less resistance to the needle than the surrounding fascia.

It may be that Mr. Hughes can invariably set up a transfusion in a few minutes. I have seen the most experienced surgeons fail to do so after a much longer time. Indeed venous spasm or unsuitable veins may necessitate cutting down.

Two small points in technique may be mentioned. Firstly warming the limb, and secondly light tapping over a vein will often result in dilation of the latter.

The advantages of the cannula-needle, as described, are as follows:

1. The incidence of post-transfusion venous thrombosis is less, because the blunt cannula does less harm to the vascular endothelium than a sharp needle point.
2. Entry into a tortuous vein is possible. It is impossible to thread a needle along such a vein, which may be the only one available.
3. If the cannula becomes blocked, another can be inserted through the external needle remaining in the vein. This saves the patient the unpleasantness of another vein puncture.

Lastly I would mention that an intermittent intravenous drip is not always due to faulty technique, but may be caused by venous spasm. A few drops of nikethamide injected into the tube will overcome this spasm almost immediately but not necessarily permanently.

London, W.1. F. R. ELLIS.

SIR,—It was very refreshing to read Mr. Hughes's letter of Dec. 17 about the much-debated intravenous cannula and its method of insertion. Perhaps I may point out a few additional requirements for successful operation:

1. The needle must be really sharp. Blunt needles automatically cause more damage to the vein, increasing the chance of a hæmatoma, venous spasm, and subsequent thrombosis.

2. Mr. Hughes's illustration shows a 45° bevel, but he does not point out the importance of this. Many transfusion needles are machined with a concave end, which often terminates in a useless spike. It is extremely easy to transfix a vein, however well distended, with such a weapon. Further, the intima is readily lacerated when the needle is advanced up the vein.

3. A fine, slow, lateral tremor transmitted from the operator's hand to the needle-tip helps to prevent accidental laceration of the intima during final advancement of the needle.

Having got a "drip" successfully erected, it is timely to remember the possible causes of venous spasm; this is the nocturnal epitaph of too many well-deserving transfusions. For trouble-free and protracted transfusion the 'Polythene' catheter appears to have no peer. Perhaps the simple and effective needle cannula will eventually be used for inserting this excellent innovation.

R.A.F. Hospital,
Ely, Cambs. R. N. G. ATHERSTONE.

PENICILLIN-RESISTANT STAPHYLOCOCCAL INFECTION IN A MATERNITY HOSPITAL

SIR,—The careful and comprehensive investigation by Dr. Mary Barber and her colleagues, reported on Dec. 17, brings out again the potential dangers, and the high incidence, of carriers of virulent strains of *Staphylococcus aureus* in some maternity hospitals, and the particular circumstances in which the carrier-rates may remain high despite the application of any direct method of clearance.

The intrinsic difficulties in many maternity hospitals are such that overcrowding, overwork, and improvised arrangements are likely to continue for a time; but fresh air and outdoor exercise may be of considerable value in keeping down the incidence, and severity of infection, of carriers. Whenever possible, therefore, nursing personnel should be encouraged to get out into the fresh air during their leisure-time and to make good use of the natural sunshine. The significant decrease in the number of carriers during August, 1949, in comparison with February, 1949, might have been due to improved general health and other factors arising from the seasonal advantages of summer. However, the whole story plainly indicates that any new maternity hospitals should be constructed upon a plan of reasonable dispersal and at the same time be well surrounded with a green belt so that everyone working in them shall have at least a short walk in the fresh air several times a day and every encouragement to slip out into the sunshine for a few minutes in the less busy periods of the day's routine.

To those who have responsibilities in maternity departments, Dr. Barber's findings may come as a shock, especially because of the high percentage of penicillin-resistant strains in the carriers. The report reminds us that in an overcrowded, ill-ventilated, and overworked maternity department, the newborn baby is often at the mercy of an intensely infective environment.

Department of Child Health,
University of Bristol. A. V. NEALE.

FOREIGN BODIES IN THE ABDOMEN

SIR,—Two days before Christmas I did a necropsy for the coroner on a woman of 88. In the duodenum was a diverticulum, and in this was a round black object, resembling a small button. On cleaning it we found it to be a threepenny piece, old style, minted in 1940. Obviously a relic from a previous Christmas. There was no inflammatory reaction, and it is unlikely that there had been symptoms, although the coin had probably been there for several years. The cause of death in this case was acute heart-failure, hypertension, and chronic nephritis.

Kent and Canterbury Hospital,
Canterbury. I. B. MORRIS.

VITAMIN E

SIR,—The important article by Dr. Ratcliffe in your issue of Dec. 17 mentions the wholesale condemnation of the use of vitamin E in cardiovascular disease which was released to the press, the radio, and *Modern Medicine in Canada* in November, 1946, by Dr. R. L. Noble, secretary of the Ontario College of Physicians and Surgeons. That statement has been widely quoted, of course.

It should be known that the college is purely a legal body, concerned with regulating the details of medical practice in the Province of Ontario. It has neither the power nor the facilities to decide on the merits of any medical discovery, or to pass judgment upon one. How inaccurate and misleading the statement was is now rapidly becoming apparent. Castagna and Impallomeni[1] have shown the value of α-tocopherol therapy in phlebitis. Stritzler[2] and Burgess and Pritchard[3] have corroborated its value in indolent ulcers. Its powers as a physiological and safe anticoagulant have been emphasised independently by Zierler's[4] group at Johns Hopkins and the group at Tulane,[5] the latter having already used it in the prophylaxis of thrombosis. The value of this agent in vasospasm has been made clear by Tusini,[6] and in muscle ischemia by the Manchester group.[7]

We notice that one who teaches "experimental methods" at Manchester already is convinced that what benefits were achieved "in certain cases" (citing our heart papers) we have reported could scarcely be "due to causes other than vitamin-E therapy." May we indicate that our conclusions of 1945–46 on both cardiac and vascular disease were reached by identical methods, are obviously all of a piece, and we are no more or less accurate with respect to one than the other? We patiently await the news that cardiologists, at least in the country of Lord Burleigh, have picked up the data the students of vascular disease have brought forward and have hurdled the diaphragm.

W. E. SHUTE
E. V. SHUTE.

The Shute Institute, London, Ontario.

SIR,—In their letter last August, Shute and Shute[8] assert that I found that vitamin E gives encouraging results in Buerger's disease. In my report on this subject I said[9]:

> "In the six cases of thromboangiitis obliterans, none can be considered to have shown improvement while on vitamin E. . . . vitamin E has contributed nothing

to our cases which have stopped smoking and just as ineffective in those who continued to smoke.

My experience in other cases with leg ulcers, as outlined in the paper quoted, has been that vitamin E failed to hasten the healing-time, and its use has been discontinued. There is no ambiguity regarding my stand on this controversial subject, and I resent being placed on the opposite side. Such tactics can only bring disrepute on the proponents of vitamin-E therapy.

Pittsburgh, Pennsylvania. L. LEWIS PENNOCK.

CURARE AND PRECIPITATE LABOUR

SIR,—In his letter of Dec. 10, Dr. Mills gives a fair and reasonable analysis of the conclusions reached by Dr. Rollason (Nov. 19). Most of us who have observed the uterus under local anæsthesia alone will appreciate that, as Marshall[1] has lately pointed out, the effect of curare on uterine contraction and retraction is, in comparison, probably minimal; though Malpas[2] has cited one purely mechanical contra-indication to its use which may on occasion be significant.

I therefore hope too that any further cases in which fœtal distress might be attributed to curare will be published, since my own experience leads me to the firm belief that in good hands the use of the curare-'Kemithal'-cyclopropane sequence is a valuable contribution to "cæsarean" anæsthesia. I find it, however, difficult to agree with Dr. Mills that "hæmorrhage experienced during cæsarean section under curare is considerably more than when either a local or a spinal anæsthetic is employed." On the contrary, I have observed the final stages of the operation to proceed smoothly and with a minimum of blood-loss, though I always have my anæsthetist give an ampoule of ergometrine intravenously as the head is being extracted, believing that I am not justified in withholding it.

Liverpool. H. VINCENT CORBETT.

CHANGING YOUR DOCTOR

SIR,—May I bring to notice how gravely the administration of the National Health Service is breaking down through the continuation of the present preposterous regulation by means of which everyone is free to change from one general practitioner to another whenever he wishes? It is in fact theoretically possible to have six different doctors in one week. Recently, we have seen resolutions put forward by the Ayr and Norwich executive councils recommending a return to the old system of National Health Insurance days. No doubt the new scheme had, at its inception, much in its favour, but its possible abuses were not appreciated. Now the mounting cost of the service is causing such alarm to our administrators that it might be worth reviewing the present system in comparison with the past.

In order to prevent unnecessary expenditure, a doctor's position in relation to his patients should be as independent as possible. Since his remuneration is based on the number of patients on his list, the tendency must be for him to give no incentive for patients to transfer to other doctors. Such an incentive would certainly present itself if he failed to comply with a request for: (*a*) medical certificate for incapacity for work, (*b*) authority for car and ambulance service, (*c*) recommendation for ophthalmic services, (*d*) recommendation for specialist or consultant services, or (*e*) the ordering of a particular drug or appliance; or if the doctor would not guarantee admission to a particular hospital in case of illness. There are many other incentives of a most trivial kind.

…resent arrangements the doctor is placed in a false position—who can blame him if he leaves the straight and narrow path with the possibility of his own, not the State's, insolvency at the end of it?

In case the position may seem overdrawn, let me give a few examples:

The Ambulance Service.—The mileage for one county council alone is:

1948		*1949*	
January	14,800	February	53,000
July	24,800	July	48,700
August	37,700	August	53,000
November	43,400		

The Home-help Service.—The estimate has been doubled. A special appeal has been issued to doctors to have regard to the cost and to make requests only where there is real need and where the assistance required cannot be given by relatives. This is very easy to do if the doctor himself is secure.

Executive-council Administration.—Since the new regulations started, the clerical work involved through patients changing their doctor has increased to such an extent that extra clerks have sometimes been required.

It would appear to be obvious that immediate steps must be taken to improve the situation. The simplest and easiest is undoubtedly to return to the old National Health Insurance system of permitting change only once every three months, except by mutual consent of old and new doctor.

Worthing, Sussex. HAROLD LEESON.

OPERATIONS FOR MITRAL STENOSIS

SIR,—The leading article on this subject in your issue of Oct. 29 gives the impression that the development of the surgical treatment of this condition springs entirely from American sources. The auricular approach to the stenosed valve, which is now being used with considerable success and is undoubtedly the route of choice, was used successfully by Sir Henry Souttar in this country in 1925.

A recent paper[1] mentioned that a successful direct operation for mitral stenosis had been performed at Guy's Hospital. For some three to four years our efforts have been directed towards valvulotomy for mitral stenosis and several cases have now been operated on successfully at Guy's Hospital, the first over eighteen months ago. A full report of this work is now being prepared for publication. This letter is to draw attention to the fact that this country is not behindhand in the development of surgery for the relief of mitral stenosis.

CHARLES BAKER
R. C. BROCK
Guy's Hospital, London, S.E.1. MAURICE CAMPBELL.

STERILISATION OF POLYTHENE TUBING

SIR,—Dr. Bryce-Smith's ingenious apparatus, described in your issue of Dec. 24, is of great interest to all interested in continuous spinal, spinal-extradural, or caudal-extradural methods of analgesia.

Recently, however, I received a report from another anæsthetic centre in Great Britain that a fine 'Polythene' catheter (sterilised by boiling) had broken after several hour's use during a continuous caudal analgesia for childbirth. It seems that the mobility of the skin in the sacrococcygeal region had strained the catheter at its point of entry into the sacral hiatus (where it was kept still) and it had finally fractured—leaving 2–3 in. within the sacral canal. It would appear, therefore, to be inadvisable to use fine plastic catheters for continuous caudal analgesia until they can be made in this country from materials as tough as those employed by anæsthetists in the U.S.A.

Obituary

WILLIAM HENRY NEWTON

M.D., M.SC. MANC., D.SC. LOND.

Professor Newton died on Dec. 21 in Edinburgh, where he had held the chair of physiology for only a year. His early death will be widely and deeply regretted both for his personal qualities and for his value as investigator, administrator, writer, and teacher.

Born in 1904, he was the son of the Rev. J. T. Newton. From Ashville College, Harrogate, he went to Manchester University, where he took first-class honours in physiology at the B.SC. examinations in 1925 and graduated as M.SC. a year later after a period of study on smooth muscle with the late] B. A. McSwiney. This work he continued during the clinical years before he qualified in medicine in 1929. The longest spell of his academic life was some 14 years spent at University College, London, where, with an interval in 1937–38 as Rockefeller travelling fellow at Yale University, he was in succession Sharpey scholar, lecturer, senior lecturer, reader in physiology, and sub-dean of the faculty of medical sciences. In 1934 he took his M.D. Manc. and in 1940 his D.SC. Lond. From 1939 to 1944, as acting head of the department of physiology during the absence of Professor Lovatt Evans, he clearly showed his worth: despite rather unstable health, he conducted the department with tact and wisdom under the trying conditions of evacuation, first at Cardiff and later at Leatherhead. Of Newton as chief a colleague writes: "He was a man who was loved as well as respected. His manner was unassuming, and his kindness and human understanding were obvious at first sight. He considered others and consulted their wishes, though this did not mean that he was incapable of coming to decisions or of making up his own mind. A department run by Newton was a happy department, because his own character was both strong and charitable."

In 1944 he was appointed to the Holt chair of physiology in the University of Liverpool, where he was responsible for great changes in the physiological work. In 1948 he was invited to the chair at Edinburgh, which he accepted, though not without some heart-searching, perhaps because of the opportunity which this change offered him of rejoining his former colleague, Professor G. F. Marrian. He first fell ill last May; so his new university had not long to learn to know him; but he had already won affection and respect. L. M. P. writes: "He came at a time when the preclinical syllabus was being replanned. It was quickly apparent that he knew what needed to be done, and that he was willing and anxious to coöperate with other departments so that the syllabus might be a well-knit whole. Though his time with us was short his power to teach lucidly and hold interest made an impression. It was at once evident that he was a good and considerate head of department. He kept his courage and sense of humour even when he knew the meaning of his illness."

In his research Newton was conspicuously patient and self-critical, and his results could always be accepted with the fullest confidence. His interest in reproductive endocrinology was first roused by some observations made with Professor Marrian on weight changes in mice during pregnancy, which showed that mice may be physiologically pregnant in the absence of fœtuses provided that the placentæ are retained. Later observations by Newton and other workers showed that pregnancy could persist in the absence of the ovaries in certain species which include the guineapig, horse, monkey, and man, and suggested that in these species the œstrogen and progesterone necessary for the maintenance of pregnancy is supplied from an extra-ovarian source—probably the placenta. His work with Beck and Richardson made it clear that the placenta plays a part in mammary development, which is largely independent of both ovaries and pituitary. With his associates he was also interested in the activity of relaxin and œstrogen in the separation of the pubic bones.

But Newton's abilities went far beyond the ploughing of a single furrow, and there were few fields of physiology with which he did not have a sound and broad acquaintance, as the contents of his new edition of *Recent Advances in Physiology* showed last year. In writing a book of this kind there is a temptation to take shelter behind one's own specialist knowledge and to produce yet another specialist monograph. But, except for the chapter on the physiology of pregnancy, the book deals with a wide [illegible] from temperature regulation to colour-vision, which lay well away from his own interests. Later he published his own *Introduction to Physiology*.

In 1931 Newton was elected a member of the Physiological Society, and he served it with characteristic zeal and loyalty as secretary (1943–47) and later as chairman of the committee, when his good judgment showed to advantage and his pleasant sense of humour often lightened the proceedings. He often spoke at meetings, and his last communication, jointly with A. D. Dewar, was on the programme for Dec. 17. As a member of the editorial board of the *Journal of Physiology* (1948–49), his ability to give the essence of a subject briefly and clearly was of great value. As head of a department he had learnt to pull together loosely written papers, and to the inexperienced writer he used to say "When you are sure of your facts express yourself definitely, not hesitantly." Many of his friends recognised his contribution in 1939, from A Physiologist in America, to THE LANCET series, "Grains and Scruples"; for, as C. L. E. points out, "Bill Newton wrote well and gracefully, and with a characteristic charm of style. His letters, until the last, had flashes of shrewd wit and neatly turned phrases. He had fine discrimination in art and a talent in making water-colour drawings which were vigorous and effective. . . . He belonged to a generation of physiologists which, for one reason or another was already too small in number, and among them he was outstanding."

A. S. P. writes: "Newton was known to many of his students as 'friend Newton,' and in such matters students are discerning people. He was essentially a friendly person, restful, unassuming, and helpful on every occasion, with the same quiet easy manner for the newest laboratory assistant as for the most distinguished figure of the academic world. With all this he had great qualities of mind and personality—determination, originality, and scientific curiosity which showed in years of fruitful research along several different lines, and moral and physical courage which was tried to the uttermost before his death.

"Newton excelled as a teacher, especially in the practical laboratory in which he had the gift of making the routine experiments seem of vital interest and importance. The less intelligent students could always be sure of help and encouragement from him, and the more intelligent and original were stimulated to their best. With his students Newton had the greatest satisfaction that can come to a teacher, that his old students constantly returned for help and advice."

Dr. Newton married, in 1931, Stella, daughter of Mr. Roger Reynolds. His family consists of two daughters.

LANCELOT BROMLEY

M.A., M.CHIR. CAMB., F.R.C.S.

Mr. Lancelot Bromley, who died at Seaford, Sussex, on Dec. 17, at the age of 64, was the son of Sir John Bromley. He was educated at St. Paul's School and Cambridge University. He qualified from Guy's Hospital in 1909, and took the Cambridge M.B. the following year. In 1912 he obtained the F.R.C.S. and the next year the M.CHIR. In 1916 he was appointed assistant surgeon to Guy's. He took on the additional appointment of surgeon to the neurological department in 1920, which he held for a number of years, and he became full surgeon in 1933. Early in his career he was for a time warden of the residential college at Guy's, and he was dean of the medical school from 1915 to 1920. He was also on the staff of Putney Hospital and Surbiton Hospital.

The complete upheaval that the war imposed on Guy's was distasteful to his orderly mind, and he felt he could not do his best work in a makeshift communal underground theatre. While retaining most of his London appointments, in 1942 he retired from Guy's to become surgeon to the new Ministry of Pensions Hospital at Stoke Mandeville. A few years ago he gave up all his

London work, except for a regular visit to the Medical Sickness Society, of which he was the vice-president, and retired to Seaford.

"Those who had the pleasure of knowing and working with Lancelot Bromley," writes N. L. E., "could not fail to be struck, from the first meeting, by his charm of manner. Always friendly, courteous, and modest, he spoke quietly and softly, and was seldom, if ever, known to raise his voice. Even in the middle of what might be considered a very difficult and tedious operation he would never lose his composure. Few surgeons have his quality. In debate he had the facility of getting at the pith of the matter better than most men and of expressing his views quietly in clear and convincing language. These same qualities of gentleness and control pervaded all his work. At a time when many surgeons worshipped speed, Bromley was one of the first to practise a quiet unhurried technique, and taught this to his registrars and house-surgeons. He would advise his first assistant in a whisper, which the students around would be unable to hear. But he knew well that at that stage they were unable to appreciate the niceties of technique. At his outpatients he took great trouble to select the best cases for demonstration at length to his students. His ward teaching was also much appreciated. He was not often to be seen at medical meetings or committees, but when he did attend he could be relied upon to contribute to the discussion his well-reasoned arguments.

"He had always devoted his spare time enthusiastically to his family, and after he retired his life at Seaford was gladdened by the visits of his children and grandchildren, and by an occasional game of golf. A keen yachtsman, he had a boat built to his own design, and he was also a good cricketer and hockey player, and a first-class golfer, playing many times in the Amateur Championship."

Mr. Bromley is survived by his widow, formerly Miss Dora Ridgway Lee, of Dewsbury, a married daughter, and a son who has inherited much of his surgical skill and athletic prowess.

JOHN PHILIP BUCKLEY

M.C., M.D., M.S. LOND., F.R.C.S.

SOME eighty years of surgery and good fellowship has been broken in Manchester by the death of Philip Buckley on Dec. 20. His father, Sam Buckley, who qualified in 1868 and was surgeon at the Clinical (now the Northern) Hospital, could tell many a story of the doings of residents at the Manchester Royal Infirmary which brought to mind hospital tales of early Victorian times.

Philip was educated at Rugby School and Trinity College, Cambridge, where he took a first class in the natural sciences tripos in 1904. Four years later he qualified from the London Hospital, and, after holding surgical posts, took the F.R.C.S. in 1911. In 1914 he was appointed assistant surgeon to the Manchester Royal Infirmary. His work there was almost immediately interrupted by the outbreak of war, during which he served in France and the East.

As a surgeon his chief interest was in rectal work and in the treatment of hernia, in which he developed a special technique.

Buckley was popular with his students for he always had some experience to fix his teaching in their minds, and his own generation will also remember him with affection as a good teller of tales. E. B. L. recalls two of his favourite stories:

"When Buckley was stationed near Mount Sinai in the first war a report came in that some of the men on outpost duty had been poisoned by eating berries. His commanding officer suggested he should go up and investigate. Buckley thought that the commanding officer, who was a general practitioner and therefore had a wider experience, was more suitable for the task, but, after an argument, was ordered by his senior to go and report and treat. On arrival he found the plant and rather helplessly examined the berries. Then his mind wandered to far-off days when he was learning the nature of specimens kept in drawers for materia medica diagnosis at the Manchester University. 'Why, they are castor-oil beans,' he thought. He wrote a learned report, the gist of which was that if the men stopped eating the beans they would recover. For this, according to his own account, though his friends did not altogether believe him, he was awarded the Military Cross. Again, his adventure with the hippopotamus at the Zoo which he was trying to photograph and which, resenting the process, made him run the gauntlet for his life, or at any rate to avoid a full-dress ducking, along the slippery edge of her pool, was a story worth hearing. He had a good knowledge of the comparative anatomy of mammals."

JOHN EDWARD LOVELOCK

B.M. OXFD, M.R.C.P.

THE medical profession has contributed liberally to athletic history: there is not one branch of sport in which outstanding exponents cannot be identified. So far as the running-track is concerned, the name of Jack Lovelock may well be supreme for all time.

Physical prowess always incites hero-worship but alone does not always confer world-wide celebrity: there must be other special contributions to a personality. Lovelock had everything—charm, character, and intellect, as well as remarkable physical endowments, and the world has been robbed of a spectacular figure. His tragic accidental death on Dec. 28, at the age of 39, is early enough for his exploits to be within recent memory. He came from Otago University, New Zealand, to Exeter College, Oxford, as a Rhodes scholar in 1931, and gained his athletic blue as a freshman. During his first year at Oxford he established new British records for the mile and the three-quarter mile and displayed his versatility by winning the cross-country race against Cambridge in record time and in boxing for the university as a feather-weight.

In 1933, when running in America for Oxford and Cambridge against Princeton and Cornell, he won the mile in 4 minutes 7·6 seconds, a world record. Further triumphs included presidency of the Oxford University Athletic Club, an Amateur Athletic Association championship, a British Empire championship, British records at 2 and 3 miles, and, as the culmination of his career, victory in the 1500 metres race at the Olympic Games in Berlin in 1936, in world record time.

Because he was on occasion beaten in comparatively mediocre time, Lovelock was criticised as a temperamental runner—an absurd designation if intended in a disparaging sense, for great athletes like great artists are inevitably temperamental, partly as an exponent of their nature, partly from the circumstances of intense competition. Lovelock's career coincided with a plethora of mighty middle-distance runners, and good judges consider him to have been the greatest of them all. He had the anatomical proportions which produced a beautiful body balance, a perfect style, and an optimum stride with maximum rhythmic coördination and muscular economy. Moreover, a philosophic approach to the principles of training and of competition were based on a scientific foundation. When I examined him in the summer of 1935 on the eve of his departure to Princeton to run against the leading Americans in "the mile of the century" his cardiac rate was only 39 to the minute—the most infrequent I have ever encountered. His supreme fitness was accompanied by a tranquillity, a confidence, an inability to contemplate defeat. "Temperamental"—perhaps; but for the great occasions he had the capacity to mobilise all his resources. In the final of the Olympic 1500 metres in Berlin he displayed superb generalship. Early in the race he placed himself exactly as he wished, in a position from which he could dominate. Indeed, one had the impression that he was manipulating the field of champions according to his set plan.

Thenceforth he abandoned athletics to apply himself with equal resolution to the practice of his profession. He qualified B.M. in 1937 and took the M.R.C.P. in 1940. He showed himself to be, as would have been expected, a thoroughly capable physician, shrewd rather than brilliant, knowledgeable but with common sense. In the war his special knowledge and interests were eagerly utilised by the R.A.M.C., in which he worked as a specialist in physical medicine. His article in the Corps *Journal* on the problems of assessing physical fitness for hard work showed a masterly grasp of the subject expressed with a highly desirable dogmatism.

On demobilisation he was appointed director of the newly established rehabilitation department at St.

Bartholomew's Hospital. A highly successful career in a specialty for which he was so eminently fitted appeared certain; but unhappily, after a short period of enthusiastic application, he became restless, and he resigned to take an appointment in New York as assistant director of physical medicine and director of rehabilitation at the Hospital for Special Surgery. In this he appeared contented and energetic, though he suffered from persistent diplopia and frequent headaches. Early in the war he had sustained a severe hunting accident with concussion and a far more serious cerebral injury than he was willing to admit.

ADOLPHE ABRAHAMS.

Dr. Lovelock married, in 1945, Miss Cynthia Wells James, of Brooklyn, who survives him with two daughters.

CLIFFORD DOBELL

M.A., SC.D. CAMB., F.R.S.

Dr. Dobell, who died in London on Dec. 23 at the age of 63, was protistologist to the Medical Research Council. Earlier he had held a lectureship and assistant professorship in protistology and cytology at the Imperial College of Science. His work on amoebic dysentery during the 1914–18 war was summarised in his Medical Research Council reports on the protozoological investigation of cases and carriers in 1917, and his study of 1300 convalescent cases in 1918. During the late war he continued his researches on the intestinal amœbæ of man: he completed his study of the life-history of *Endolimax nana*, and he was able to cultivate iodamœba in vitro for the first time. His early studies of coprozoic flagellates are also well known and of acknowledged value. One of his outstanding contributions was his study of the life-cycle and of the nuclear changes in the parasitic sprozoon *Aggregata eberthi*. While other workers did not entirely agree with his interpretation, it remains a classic of this kind of investigation.

Though Dobell was a protozoologist he also did important work in bacteriology, and did much to lay the foundation of a more academic and cytological approach to the study of bacteria in general. For many years the science of bacteriology suffered from the study of the pathogenic forms by medical men with, naturally enough, little interest in the finer structure of the organisms. Dobell's mastery of technique and his able use of the microscope, as well as his choice of some of the larger free-living forms as objects of study, opened up an approach to bacteriology which has now been followed in many directions.

Dobell was devoted to science, but he belonged to an earlier tradition and he accepted the modern experimental and biochemical approach with considerable reluctance.

Sir CHARLES GORDON-WATSON

D. R. C. writes: "Sir Charles Gordon-Watson came to York early in the war as surgical consultant to Northern Command. He was one of the first of a galaxy of talent which descended on York Military Hospital, and which transformed it into one of the most efficient units in the country. From then until his retirement he ranged over nearly half of Eastern England, visiting hospitals and dealing with major surgical problems and policy. He stayed on in York when he retired, liking the old city and its racecourse. His tall figure and his imperious but kindly features were well known in the town and on the golf course.

"Two years ago he had a major abdominal operation, done by one of his old Bart's juniors. This was very successful, and it was hoped he would have many years of active life, but despite a new eupepsia other signs of the wear and tear of a busy surgical life showed themselves. He fought his disabilities with great courage; only a few months ago he started having a new course of golf lessons. Later, when his limbs wouldn't quite obey his commands, he would practise movements for hours, and by his strong will force his legs to carry him in some sort of fashion. Even to those who knew him only in his later years it was plain that here was a commanding personality and a good and skilful surgeon."

A requiem mass for Sir Charles Gordon-Watson will be held at St. James's, Spanish Place, London, W.1, on Wednesday, Jan. 11, at 11.45 A.M.

Appointments

Adeney, N. F., M.B. Camb., F.R.C.S.: director of thoracic Southampton.

* Alergant, C. D., M.D. Lpool, M.R.C.P.: consultant venereol Liverpool region.

Crawshaw, D. G., M.B. Manc., D.C.H., D.P.H.: M.O.H., Peterbor

Curtis, Gladys, M.R.C.S.: asst. school M.O., Sheffield.

Darke, C. S., M.D. Lond., M.R.C.P.: consultant physician, General Hospital, and physician, thoracic surgical Sheffield.

Friel, W. R. N., M.B. Edin., M.R.C.P.E., D.P.H.: medical sup tendent, All Saints' Hospital and Hill Top Hospital, Br grove, Worcestershire.

Glanville, H. J., M.R.C.S., D.PHYS.MED.: consultant physicia physical medicine, Salisbury Hospital Management Comm area.

Hutton, T. B., M.A., M.B. Camb., F.R.C.S.E., D.L.O.: ear, nose, throat surgeon (consultant), Castleford and in Wakefield A group.

Lloyd, T. W., D.M. Oxfd, M.R.C.P.: medical superintendent consultant chest physician, South Worcestershire grou hospitals and St. Wulstan's Hospital, Malvern.

McLeod, W. J., M.D. Belf., D.P.H.: senior M.O., Belfast co borough health committee's establishment.

Mulvein, Margaret, M.B. Glasg.: asst. M.O. for the staff o County Council of Yorkshire.

Middlesex Hospital, London:

Boyle, A. C., M.B. Lond., D.PHYS.MED.: asst. physician, de physical medicine.

Lloyd-Davies, O. V., M.S. Lond., F.R.C.S.: asst. surgeon.

Snelling, Margaret, M.D. Lond., M.R.C.P., F.R.C.S.: radiotherapist.

* Amended notice.

Births, Marriages, and Deaths

BIRTHS

Atkinson.—On Dec. 18, at Beckenham, Kent, the wife of Dr. W. J. Atkinson—a daughter.

Boreham.—On Dec. 30, in London, the wife of Mr. Peter Boreham, F.R.C.S.—a daughter.

Bradmore.—On Dec. 22, to Dr. Rosemary Bradmore, wife of Mr. H. M. Bradmore, F.R.C.S.—a son.

Devas.—On Dec. 21, in London, the wife of Dr. M. B. Devas—a son.

Elsom.—On Jan. 1, at Lichfield, the wife of Dr. A. R. Elsom—a son.

Gladstone.—On Dec. 26, in London, the wife of Dr. G. S. Gladstone—a son.

Hayden.—On Dec. 26, the wife of Dr. R. K. Hayden—a daughter.

Headley.—On Dec. 22, in London, the wife of Dr. S. R. T. Headley—a son.

Lennox.—On Dec. 19, in London, the wife of Dr. Bernard Lennox—a son.

MacKeith.—On Dec. 20, in London, the wife of Dr. R. C. MacKeith—a son.

Morgan.—On Dec. 20, in London, the wife of Dr. G. O. Morgan—a daughter.

Pennington.—On Dec. 24, the wife of Dr. M. C. Pennington—a daughter.

Pringle.—On Dec. 14, the wife of Dr. Edward Pringle—a daughter.

Vowles.—On Dec. 25, at Barnstaple, to Dr. Mary Vowles, wife of Dr. Keith Vowles—a son.

Walker.—On Dec. 22, the wife of Dr. M. F. C. Walker—a daughter.

MARRIAGE

Chivers—Corbishley.—On Dec. 30, at High Lane, Cheshire, Charles Peter Chivers, M.B., to Jean Corbishley.

DEATHS

Chaplin.—On Dec. 25, Clement Woodthorpe Chaplin, M.D. Lond., aged 74.

Clarkson.—On Dec. 16, at Watford, Colin Campbell Clarkson M.B. Lond.

Cruden.—On Dec. 24, in London, Robert Cruden, M.A., M.B. Aberd.

Lovelock.—On Dec. 28, in New York, John Edward Lovelock, M.A., B.M. Oxfd, M.R.C.P.

McRobert.—On Dec. 28, at Rangoon, Burma, Ronald McRobert, M.B. Aberd., F.R.C.O.G., lieut.-colonel, I.M.S. retd, aged 53.

May.—On Dec. 22, at Westerham, P. M. May, M.R.C.S., surgeon captain, R.N. retd.

Mulvany.—On Dec. 23, in London, Thomas Edward Mulvany, M.R.C.S., aged 81.

Murray.—On Dec. 31, at Hythe, Kent, John George Patrick Murray, M.D. Edin., F.R.C.S.E.

Newton.—On Dec. 26, in Edinburgh, William Henry Newton, M.D. Manc., D.SC. Lond.

Pare.—On Dec. 25, at Harrogate, Henry Burton Pare, M.B. Manc.

Pead.—On De John Hunter Pead, B.A., M.B. Camb d, aged 81.

Pesel.—On De M.C., M.D. Edin., aged 72.

Platt.—On D Noble Platt, M.R.C.S., aged 78.

Scales.—On Dec. 21, in London, Cuthbert Scales, M.C., M.B. Edin., colonel, R.A.M.C. retd.

Unitt.—On Dec. 22, at Leicester, James Arthur Unitt, L.R.C.P.E., aged 89.

Upcott-Gill.—On Dec. 31, at Ryde, I.O.W., Geoffrey Allen Upcott-Gill, F.R.C.S.E., aged 71.

Wolverson.—In December, at Folkestone, Frederick Wolverson, M.D. Glasg., aged 75.

THE EARLY YIELD OF HUMAN MILK, AND ITS RELATION TO THE SECURITY OF LACTATION

HAROLD WALLER
M.B. Camb.
PÆDIATRICIAN, BRITISH HOSPITAL FOR MOTHERS AND BABIES, WOOLWICH

STATISTICAL reviews of methods of infant feeding have shown conclusively that nearly half the babies born in this country are bottle-fed by the time they are three months old. There is no certain knowledge why this is so, and it seems to be accepted by many as a social phenomenon related in some way to the habits of women and their conditions of life. Opinions on the causes differ, and differ chiefly on whether women are truly incapable of yielding enough milk to meet the requirements of breast-feeding or are merely unwilling to undertake the task. The necessity for wage-earning soon after childbirth is admittedly far less than in the past, though it still applies with special force to the unmarried mother. If we exclude the category due to separation of mother and child, we are still left with many thousands of whom we need to know how many are truly incapable of breast-feeding and how many needlessly give it up.

From time to time something fresh emerges from the surveys, such as that the failure to breast-feed is not related to differences in social status [1]; that the time at which the change is made to artificial feeding varies in different localities [2]; and that women delivered in hospitals are slightly more successful than those delivered in their own homes.[1] The chief value of findings such as these is in checking opinions which easily gain currency, but I think it unlikely they will do more. For it is in the nature of things that from almost whatever motive a woman resorts to artificial feeding she will say she lost her milk. It also happens that, if she ceases to breast-feed either wholly or in part, it is not long before this statement will be true. Should the change precede the inquiry, it must often be pure conjecture whether it was made of necessity or for some other reason.

Those who contend that many women are physically incapable of producing enough milk for their babies do not often define just what they imply by this incapacity. It could, for example, refer to a lack of enough secretory tissue in the breasts. This is very difficult to assess by physical signs, but some evidence should be afforded by measurement of the yield at the start of lactation. An attempt to do this is described here. On the other hand, despite a sufficient yield at the beginning, failure could arise from an inability to maintain it. There are many difficulties in prolonging regular measurements of yield beyond the lying-in period, and I have not been able to include any here. There are, however, certain features of lactation in the early phase which appear to have an influence on its subsequent security. One of these has been chosen for discussion.

PREPARATION FOR BREAST-FEEDING

Before giving details of the measured yield of a series of women delivered in this hospital, two ways must be mentioned in which their supervision probably differs from what is usual elsewhere. Both concern preparation for breast-feeding.

All are examined early in pregnancy for a defect of the nipples which, even in slight degree, is a hindrance to getting the newborn to take the breast and if at all pronounced may wholly frustrate its attempts to feed. The defect is developmental: the nipple, instead of being loosely attached to the breast and forming, as it were, merely a thickened prolongation of the areola, is more or less anchored to the underlying structures. It then reacts to pressure between the child's jaws by retracting towards the breast instead of projecting into its mouth. The defect is not revealed by mere inspection but is easily detected by compressing the areola between finger and thumb just behind the nipple's base, a test which forms a fair imitation of the baby's grasp. Applied as a routine, this test reveals in rather more than a third of our patients in their first pregnancy enough defect in one or both nipples to threaten difficulty. In all but a few correction, or at any rate much improvement, can be got by the use of a hemispherical glass or plastic shield with a circular opening in its base. The shields are worn under a well-fitting brassière which presses the nipples through the opening and gradually stretches and loosens their attachment. Some may have to wear the shields throughout pregnancy to obtain the necessary change. As a result of their use the handicap of the inverted or retracting nipple scarcely applies to the women whose lactation is considered here.

Further, all in their first pregnancy and any who have already met with feeding difficulties are taught how to use their hands so that they will be skilled in expressing milk and should need little help from the nurses in the lying-in wards. Starting not later than the 32nd week of pregnancy they are instructed to practise the expression of colostrum for ten minutes daily.

ESTIMATION OF YIELD OF MILK

For several years it has been a routine practice in our wards to control breast tension by the manual removal of milk, using it as a means to make sure that the breasts are emptied. If by test weighing we ascertain what the baby obtains through the twenty-four hours and add to this what can be expressed from the breasts, we get an approximate value for the total yield. We find also the proportion of the yield which the baby is using. The figures given here were collected from 200 primiparæ and 200 multiparæ as they passed through the hospital, and refer to the fifth and tenth days after delivery. These days were chosen because on the fifth day fullness of the breasts is usually at its height, whereas by the tenth day feeding should as a rule be smoothly under way as a result of the milk's outflow having become free: by then also the baby's appetite may be expected to have increased, and it will have acquired skill in feeding. Between the fifth and tenth days the ratio of the baby's intake to the mother's yield should reflect these changes. It was thought best to exclude women whose babies weighed less than 6 lb. at birth, since several had to be fed by special methods because of prematurity and other causes of frailty.

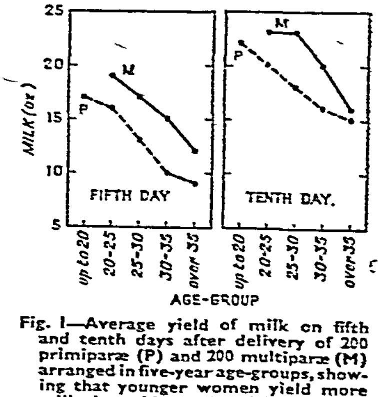

Fig. 1—Average yield of milk on fifth and tenth days after delivery of 200 primiparæ (P) and 200 multiparæ (M) arranged in five-year age-groups, showing that younger women yield more milk than older and multiparæ more than primiparæ.

Obstetrically I believe the series can be taken as representative of women who register for admission to the hospital: 2 required cæsarian section; 18 instrumental delivery; 17 had pre-eclamptic toxæmia, in 10 of whom it was classified as moderately severe; 2 had

* Amended notice.

Births, Marriages, and Deaths

BIRTHS

ATKINSON.—On Dec. 18, at Beckenham, Kent, the wife of Dr. W. J. Atkinson—a daughter.

BOREHAM.—On Dec. 30, in London, the wife of Mr. Peter Boreham, F.R.C.S.—a daughter.

BRADMORE.—On Dec. 22, to Dr. Rosemary Bradmore, wife of Mr. H. M. Bradmore, F.R.C.S.—a son.

DEVAS.—On Dec. 21, in London, the wife of Dr. M. B. Devas—a son.

ELSOM.—On Jan. 1, at Lichfield, the wife of Dr. A. R. Elsom—a son.

GLADSTONE.—On Dec. 26, in London, the wife of Dr. G. S. Gladstone—a son.

HAYDEN.—On Dec. 26, the wife of Dr. R. K. Hayden—a daughter.

HEADLEY.—On Dec. 22, in London, the wife of Dr. S. R. T. Headley—a son.

LENNOX.—On Dec. 19, in London, the wife of Dr. Bernard Lennox—a son.

MACKEITH.—On Dec. 20, in London, the wife of Dr. R. C. MacKeith—a son.

MORGAN.—On Dec. 20, in London, the wife of Dr. G. O. Morgan [illegible]

[illegible] 24, the wife of Dr. M. C. Pennington [illegible]

[illegible] wife of Dr. Edward Pringle—a daughter.

[illegible] Barnstaple, to Dr. Mary Vowles, wife of [illegible] son.

[illegible] wife of Dr. M. F. C. Walker—a daughter.

MARRIAGE

CHIVERS—CORBISHLEY.—On Dec. 30, at High Lane, Cheshire, Charles Peter Chivers, M.B., to Jean Corbishley.

DEATHS

CHAPLIN.—On Dec. 25, Clement Woodthorpe Chaplin, M.D. Lond., aged 74.

CLARKSON.—On Dec. 16, at Watford, Colin Campbell Clarkson, M.B. Lond.

CRUDEN.—On Dec. 24, in London, Robert Cruden, M.A., M.B. Aberd.

LOVELOCK.—On Dec. 28, in New York, John Edward Lovelock, M.A., B.M. Oxfd, M.R.C.P.

MCROBERT.—On Dec. 28, at Rangoon, Burma, Ronald McRobert, M.B. Aberd., F.R.C.O.G., lieut.-colonel, I.M.S. retd, aged 53.

MAY.—On Dec. 22, at Westerham, P. M. May, M.R.C.S., surgeon captain, R.N. retd.

MULVANY.—On Dec. 23, in London, Thomas Edward Mulvany, M.R.C.S., aged 81.

MURRAY.—On Dec. 31, at Hythe, Kent, John George Patrick Murray, M.D. Edin., F.R.C.S.E.

NEWTON.—On Dec. 20, in Edinburgh, William Henry Newton, M.D. Manc., D.SC. Lond.

PARE.—On Dec. 25, at Harrogate, Henry Burton Pare, M.B. Manc.

PEAD.—On Dec. 21, at Bexhill-on-Sea, John Hunter Pead, B.A., M.B. Camb., surgeon captain, R.N. retd, aged 81.

PESEL.—On Dec. 29, Howard George Pesel, M.C., M.D. Edin., aged 72.

PLATT.—On Dec. 26, at Wilmslow, John Noble Platt, M.R.C.S., aged 78.

SCALES.—On Dec. 21, in London, Cuthbert Scales, M.C., M.B. Edin., colonel, R.A.M.C. retd.

UNITT.—On Dec. 22, at Leicester, James Arthur Unitt, L.R.C.P.E., aged 89.

UPCOTT-GILL.—On Dec. 31, at Ryde, I.O.W., Geoffrey Allen Upcott-Gill, F.R.C.S.E., aged 71.

WOLVERSON.—In December, at Folkestone, Frederick Wolverson, M.D. Glasg., aged 75.

average strength and vigour can be relied on to accomplish it. How to discover whether it does so, and what to do if it fails, is not so clear.

RESIDUAL MILK

Of the 400 women in the series, 312 were yielding 20 oz. or more by the tenth day, of whom 78 reached or exceeded 30 oz.: 200, or exactly half, the babies weighed 8 lb. or more at birth. These larger babies took on average, about 17 oz. by the tenth day: not many were taking more than 20 oz., and it is unusual for those of lower birth weights to do so. It follows that at this date many of the women had some residual milk after their babies had fed; and, when this is removed by hand, it is often surprising to find how small a proportion of the total yield the child can use. Indeed, the high figures of residual milk on many of our patients' charts sometimes provoke the comment that the practice of removing the excess may well be responsible for artificially raising the yield. In my belief this is not so: it does no more than allow the breasts to reach full secretion by lowering tension and easing the milk's outflow. The range of variation (fig. 3), with the great preponderance of those falling within the 20 oz. and 25 oz. groups, does not suggest an artificial effect, and there is support for this when we turn from averages to individuals.

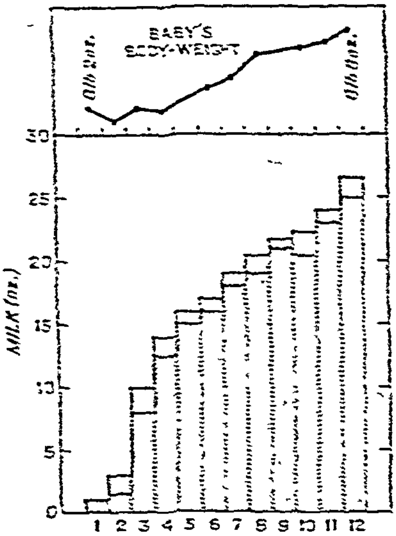

Fig. 4—Start of breast-feeding in a 3-para aged 25: hatched columns, milk taken by baby; stippled columns, residual milk. Baby was vigorous and milk outflow free. Almost whole yield was taken, and baby was getting 40 calories per lb. of body-weight by twelfth day. In such a case lactation is safe.

The example in fig. 4, a woman in her third lactation, is very typical of the start of breast-feeding when the yield is sufficient, the flow easy, and a vigorous baby takes practically the whole contents of the breasts. Here indeed the residue is so small that there is no need for it to be taken off, though in practice it is wise to ascertain for a few days consecutively that the child does achieve this degree of emptying. (This does not involve measuring either intake or residue, but merely testing if the breasts have been drained at the end of the feeds.) By contrast fig. 5 is from one of the high yielders, and here, though the baby takes a full allowance and is getting 63 calories per lb. on the tenth day, the residual milk removed in twelve days exceeded what was taken by 55 oz. It will be seen that expression of the small surplus from the first of these two women does not send up her yield to anything approaching that of the second; and further, that when secretion is truly deficient (as in fig. 6), no amount of stripping by hand will increase productivity: nor do I know anything that will. These extremes of high and low yield represent differences in the amount of glandular tissue present, as Engel[3] has shown, and I believe we can assume that a woman's potential yield is decided by the time she reaches term, and indeed earlier, as we see after premature delivery, and that it has been determined by the degree of hormonal preparation during pregnancy.

The course of breast-feeding in this series of women cannot be given: the figures were taken from patients who had passed through the hospital some months previously, and were collected with the sole object of calculating the early yield. Two other series of primiparæ, one of 100 and one of 300, have been closely followed, and of the whole number 77% were found to be successfully breast-feeding at six months without the necessity of using supplementary milk. This corresponds almost exactly to the number of those in the present series who were yielding 20 oz. or more at the tenth day. It will be remembered that the number feeding at six months has been estimated at 40% for the country as a whole.[4] It is difficult to suppose that those coming to our hospital are endowed with powers of lactation superior to the average, and any advantage they may possess in maintaining their yield is, I suggest, more likely to depend on the steps taken to keep milk tension low in the early phase. It is commonly taught that overloading of the breasts in the puerperium is of little consequence beyond causing temporary discomfort: that, if they are "left well alone," secretion soon adapts itself to the needs of the child. Now, it is true that on this plan the yield always falls; but the contention that it declines conveniently and exactly to the point at which it coincides with the child's requirements, *and declines no further*, is seriously open to question. It needs to be subjected to very much more careful investigation than, so far as I am aware, it has received.

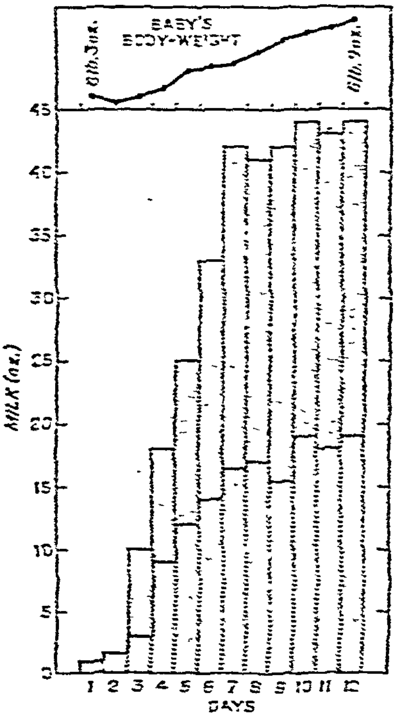

Fig. 5—Start of breast-feeding in a young primipara with a high yield of milk and small baby: hatched columns, milk taken by baby; stippled columns, residual milk. Ratio of intake to yield over first twelve days was 42%. Overloading was prevented by manual removal of residual milk. In such a case only with care is lactation safe.

At any infant welfare centre throughout the country can be met women whose infants are artificially fed by the age of a month or little more, and who give as the reason that their milk left them. It may take a little trouble to seek beyond this laconic statement for an account of what preceded the loss, but it is impressive how many tell of pain and overloading in the first week, of damage to the nipples and the difficulty of getting the

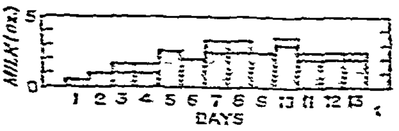

Fig. 6—Milk yield of a primipara aged 35, with virtual agalactia. Her baby weighed 8 lb. 14 oz. at birth. Only 22 oz. of milk was yielded in twelve days. In such a case breast-feeding is impossible.

---

[3] Engel, S. Ergebn. inn. Med. Kinderheilk. 1925, 24, 210.

[4] Ministry of Health, Rep. publ. Hlth med. Subj. 1944, no. 91.

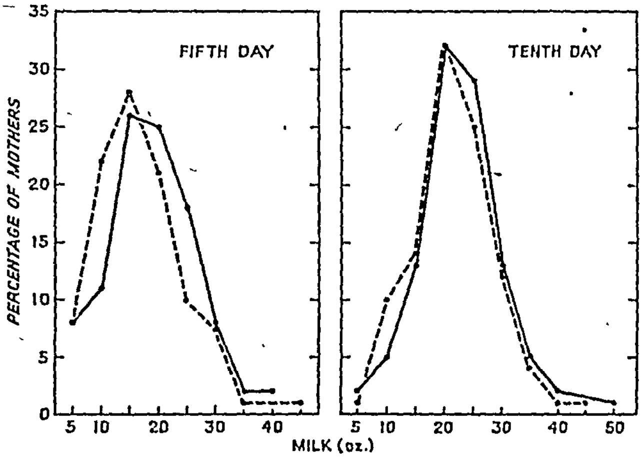

Fig. 2—Range in variation of milk yield: by fifth day 138 (69%) of primiparæ and 161 (80·5%) of multiparæ yield 15 oz. or more; and by tenth day 150 (75%) of primiparæ and 162 (81%) of multiparæ yield 20 oz. or more.

placenta prævia; and 38 had had postpartum hæmorrhage exceeding 20 oz. There was an average number of perineal lacerations needing repair. With few exceptions our patients are out of bed on the third day after delivery and move freely about the wards and nurseries by the sixth. The average stay in hospital after delivery was a fraction under thirteen days.

In fig. 1 the yield of both sets on the fifth and tenth days is shown, the women being placed in age-groups of five years. The younger produce more than the elder, and the multiparæ more than the primiparæ.

In fig. 2 is plotted the range of variation in yield, the salient points of which are as follows:

Yield	*Primiparæ*	*Multiparæ*
5th day:		
15 oz. or more	69%	80·5%
10–15 oz.	23%	11·5%
Less than 10 oz.	8%	8·0%
10th day:		
20 oz. or more	75%	81·0%
15–20 oz.	13%	12·0%
10–15 oz.	10%	5·5%
Less than 10 oz.	2%	1·5%

The proportion of the total yield which the babies take is shown in fig. 3, where the grouping is according to their birth weights. The findings are given in greater detail in the accompanying table.

The higher yield of the younger women has already been noted and reflects our general experience, as does the finding that women produce less in the first lactation than subsequently. The outstanding fact is that three-quarters of the primiparæ and four-fifths of the multiparæ (312 or 78% in all) are yielding 20 oz. or more by the tenth day—i.e., enough milk to provide a 9 lb. baby with 44 calories per lb. of its birth weight. Of the remainder, 50 (12·5%) yield 15–20 oz., which is comparatively low, and 38 (9·5%) must be called seriously deficient. There were 7 of these with virtual agalactia.

PROPORTION OF TOTAL YIELD OF MILK TAKEN BY BABIES

No. of babies	Birth weight (lb.)	Av. intake on 5th day (oz.)	Proportion of yield (%)	Av. intake on 10th day (oz.)	Proportion of yield (%)
Primiparæ					
37	6	8·6	58	13·6	73
79	7	8·6	65	14·2	75
63	8	9·8	67	14·8	78
21	9	9·2	67	15·8	83
Multiparæ					
24	6	8·5	59	13·7	71
60	7	10·6	69	15·7	83
69	8	11·7	73	16·6	83
47	9	12·4	69	17·1	83

Turning to the ratio of the babies' intake to the mothers' yield (fig. 3), with one exception the proportion on the fifth day is low for both small and large babies, ranging between 58% and 69%. By the tenth day the ratio has risen: those in four of the heaviest groups are all taking over four-fifths (83% of the yield); those in the next heaviest group about three-quarters (75–78%); the 6 lb. babies take less (71–73%). Converting these amounts into calories, the 6 lb. babies, both first and later born, are getting on average 48 calories per lb. on the tenth day, whereas the heaviest firstborns get 35 and the later born 38 calories per lb.

To summarise, these figures, so far as they go, lend no support to the opinion that a high proportion of women are physiologically incapable of producing enough milk to nourish their babies. Rather do they point to most failures being dependent on an inability to maintain an initially high yield. At the tenth day of life the smallest babies are the best nourished but take the lowest proportion of what their mothers are yielding; the converse applies to the largest babies.

It is mainly the second of these two findings—the ratio of the amount the babies take to what their mothers yield—which I propose to discuss, and, since I have not been able to find other figures for comparison, it must be assumed that they are reasonably representative. If anything, the ratio is likely to be above rather than below the average, from the care taken to keep milk tension low. The significance placed on the ratio is based on the fact, well-established in dairy science, that regular emptying of the mammary gland is a condition of continued milk secretion, and that insufficient removal of milk lowers the yield and can bring production to an end. This sequence seems to be closely related to the degree of milk-pressure within the alveoli; there seems to be a level above which it should not rise or, at any rate, above which it should not persist. Sections of the gland loaded with milk show that the secreting cells are flattened, in which state their nutrition is probably lowered and their productivity reduced, for it is known that the rate of secretion slows down progressively as the hours after milking extend.

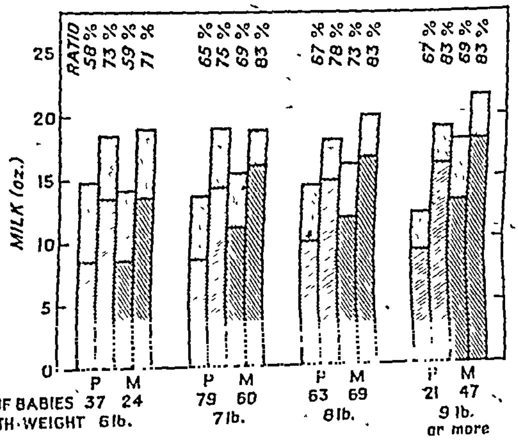

Fig. 3—Ratio of milk taken by babies to total yield by mothers on fifth and tenth days: hatched columns, milk taken; stippled columns, residual milk; P, primiparæ; M, multiparæ. Alternate columns are for fifth and tenth days.

In women, therefore, we may assume that the breasts should be drained when, or soon after, the optimal amount of milk has accumulated, and that a threat to production arises if the optimum is exceeded, or if emptying is incomplete. The time-honoured maxim that the baby should empty the breasts when it feeds is thus sound; but the usual implication is, I think, that any infant of wide-bore needle. The exudate was usually turbid, often clotted, and had a pH of about 7·4; under the microscope it was seen to contain leucocytes and small oily droplets. Turpentine might be expected to cause some pain at the sites of injection, but careful observation of the animals throughout the experiments clearly showed that the small amounts used did not produce any appreciable discomfort.

The exudate did not inhibit the growth of the strain of hæmolytic streptococcus used in the penicillin assay. Samples of exudates withdrawn in the preliminary tests from three rabbits, to which 1 unit of penicillin per ml. was added, did not inactivate the penicillin in 6 hours at 37°C.

Penicillin K and the mixture of F and dihydro F were obtained by chromatography on a buffered silica column and extraction and precipitation with cyclohexylamine. hey were identified by the microchromatographic nalytical technique now regularly used on production atches.

RESULTS

Aqueous Solutions.—In the first experiment the enicillin contents of blood and exudate were estimated after intramuscular injection of 30,000 units of aqueous solutions of crystalline sodium or amorphous calcium penicillin into rabbits each weighing about 2·5 kg. The results (table I) show that detectable amounts of penicillin remain in the blood-stream for about 3 hours, but that they are present in the damaged tissue for 8 or 9 hours. Injections of crystalline and of amorphous penicillin produced similar levels in both the blood and the tissues

Suspensions in Oil and Beeswax.—In table II are given the penicillin levels found in blood and tissue exudate after intramuscular injection of 30,000 units of penicillin suspensions (crystalline sodium or amorphous calcium) in oil and beeswax. Penicillin levels were recorded in the blood up to 12 hours and in the tissue exudate for more than 18 hours. The penicillin levels were higher in the exudates after 11 or 12 hours than after 7 or 8 hours; this may be explained by the fact that the former were taken at night, when the rabbits were resting. In this experiment, again, no appreciable difference was noted between the effects of crystalline and of amorphous penicillin.

Procaine Penicillin.—Similarly, the concentrations of penicillin were determined in blood and tissue exudates after the intramuscular injection of procaine penicillin

ABLE I—PENICILLIN LEVELS IN BLOOD AND EXUDATE OF RABBITS AFTER INTRAMUSCULAR INJECTION OF 30,000 UNITS IN AQUEOUS SOLUTION

newborn to feed; how often they say "he didn't seem able to get the milk out." Later came the discovery of a considerable loss of weight, test-feeds that recorded negligible amounts, and supplementary milk given to make good the deficiency. Soon afterwards the breasts were noted to have got smaller, and we are told "I could see he was not getting on." His reluctance to feed there and strong preference for bottle-feeds was the deciding factor. Relief at the improvement in the baby's behaviour may well mask a genuine regret at having failed to breast-feed. I have already said it may be impossible to judge whether a woman's resort to artificial feeding was optional or necessary, but when this history is obtained, especially if the skin covering the breasts shows evidence of having been recently stretched, and if involution has been rapid, it strongly suggests that failure has been the result of overloading and stasis. It should at least be borne in mind before hastily concluding that she was unwilling to persevere, was too "highly strung," or was unequal to resuming her household tasks. Of the failures which occur somewhat later and help to swell the number at three months, I suspect that many represent a more gradual decline in yield from incomplete emptying and the substitution of one or two bottle feeds, thus instituting the changes which normally accompany weaning.

If the facts presented here are correct, the variations in yield, and the small contribution to emptying the breasts which many newborn infants can make call for reconsideration of the customary management during the lying-in period. This involves the acceptance by those in charge of a greater responsibility for the results of breast-feeding beyond this stage; the more so since so many women are discharged from maternity wards while still in this critical phase of lactation. Until this acceptance becomes general I can see no prospect of an improvement in the proportion of babies likely to be breast-fed for as long as three months. To a mother the immediate progress of her newborn is always a matter of urgency, yet in present conditions the resort to artificial milk is by far the easiest solution of any difficulty she encounters in her attempt to breast-feed.

SUMMARY

The early yield of milk in 400 women was measured at the fifth and tenth days after delivery. The figures reveal considerable variation both in yield and the proportion taken by the newborn.

Of the 400 women, 78% were producing enough milk at the tenth day to provide sufficient for a baby weighing 9 lb. at birth. Failure to maintain an adequate yield is thus a more usual cause of artificial feeding than failure to secrete enough at the start of lactation.

It is suggested that insufficient emptying of the breasts in the early days after delivery is a common reason for a rapid decline in yield and may lead to its early suppression.

"... My optimism is based on the hope that all 67 nations who at the end of 1949 were members of W.H.O. and others still to join them will participate wholeheartedly, without reservations, with courage and imagination, in this great crusade for better health. I can think of no greater field for earnest, determined work. I can think of none in which it should be easier to set aside political, economic, and social differences which still divide a world which should be one world. If there is one aim which must unite us, it is surely that of making our children physically, mentally, and socially healthy. I trust that in 1950 we shall move another step forward towards building a healthier society and that in doing so we shall also give encouragement to all those who in this vital period of human history refuse to despair of mankind's destiny."—Dr. BROCK CHISHOLM, director-general, World Health Organisation, *United Nations Bulletin*, January, 1950.

PENICILLIN IN TISSUE EXUDATES AFTE INJECTION

J. UNGAR
M.D. Prague, M.R.C.S.
From the Research Division, Glaxo Laboratories Ltd., Greenfor Middlesex

IN the early days of penicillin therapy it was generall believed that its effect depended on the maintenance a threshold bacteriostatic level in the blood-strea for a sufficient time. Since penicillin is highly diffusibl aqueous solutions had to be injected continuously (b intramuscular or intravenous drip), or more usuall at intervals of 3 or 4 hours, in order to maintain th desired plasma penicillin levels throughout the course o treatment.

More recently, penicillin has been extensively used a a suspension in arachis oil containing a small proportion of beeswax or of procaine penicillin. An adequate dos of this preparation, given as a single subcutaneou injection, leaves in the tissues a depot from which th slower and continuous release of the penicillin keeps th concentration of penicillin in the blood at or abov the bacteriostatic level for a long time.

It has occasionally been reported—e.g., by Bigg (1944)—that the amounts of penicillin demonstrabl in the blood have been insufficient to explain it therapeutic effect. Experiments on laboratory animal infected with streptococci or pneumococci (Jawetz 194 White et al. 1946, Zubrod 1947) showed that the duratio of the animal's survival depends more on the total dos of penicillin injected than on the interval betwee injections. These results seemed inconsistent with th supposed need for maintaining a continuous threshol bacteriostatic level, as also did the successful treatmen of pneumonia by Tillett et al. (1944) with aqueous solu tions of penicillin given at longer intervals than thos previously recommended. This last report provided th experimental background for injecting larger doses o aqueous penicillin solutions at intervals of 12 or eve 24 hours.

Little attention seems lately to have been paid to th finding of Florey et al. (1946) that penicillin injected after severe tissue damage can be detected in the wound much longer than in the blood. Since their experience seemed also highly relevant to the beneficial effect observed with large doses given at long intervals, we undertook some experiments to show how single doses of penicillin are distributed in diseased tissues and blood.

METHOD

The method involved the production of artificial œdema in the tissue, followed by intramuscular injection of penicillin and withdrawal of blood and œdema fluid at suitable intervals for the assay of penicillin content. We first injected into guineapigs several different substances in an attempt to produce suitable localised lesions with œdema. Small amounts of turpentine gave the best results. The use of guineapigs, though satisfactory for the production of lesions, was not entirely successful, because the serum from some test animals inhibited, at higher concentrations, the growth of a strain of the highly sensitive hæmolytic streptococcus used for the assay of penicillin. Rabbits were more satisfactory, because their serum did not inhibit the test organism and blood samples in sufficient quantities could be taken from them. Moreover, in our experience the results obtained with penicillin in rabbits have reflected our findings in man.

After the injection of 0·5 ml. of oil of turpentine (*B.P.*) into the muscle of the hind leg of a rabbit, sufficient damage and œdema were produced in about 24 hours for exudate to be withdrawn. Quantities of 0·2–0·3 ml. of the exudate were aspirated with a syringe fitted with a wide-bore needle. The exudate was usually turbid, often clotted, and had a pH of about 7·4; under the microscope it was seen to contain leucocytes and small oily droplets. Turpentine might be expected to cause some pain at the sites of injection, but careful observation of the animals throughout the experiments clearly showed that the small amounts used did not produce any appreciable discomfort.

The exudate did not inhibit the growth of the strain of hæmolytic streptococcus used in the penicillin assay. Samples of exudates withdrawn in the preliminary tests from three rabbits, to which 1 unit of penicillin per ml. was added, did not inactivate the penicillin in 6 hours at 37°C.

Penicillin K and the mixture of F and dihydro F were obtained by chromatography on a buffered silica column and extraction and precipitation with cyclohexylamine. They were identified by the microchromatographic analytical technique now regularly used on production batches.

RESULTS

Aqueous Solutions.—In the first experiment the penicillin contents of blood and exudate were estimated after intramuscular injection of 30,000 units of aqueous solutions of crystalline sodium or amorphous calcium penicillin into rabbits each weighing about 2·5 kg. The results (table I) show that detectable amounts of penicillin remain in the blood-stream for about 3 hours, but that they are present in the damaged tissue for 8 or 9 hours. Injections of crystalline and of amorphous penicillin produced similar levels in both the blood and the tissues.

Suspensions in Oil and Beeswax.—In table II are given the penicillin levels found in blood and tissue exudate after intramuscular injection of 30,000 units of penicillin suspensions (crystalline sodium or amorphous calcium) in oil and beeswax. Penicillin levels were recorded in the blood up to 12 hours and in the tissue exudate for more than 18 hours. The penicillin levels were higher in the exudates after 11 or 12 hours than after 7 or 8 hours; this may be explained by the fact that the former were taken at night, when the rabbits were resting. In this experiment, again, no appreciable difference was noted between the effects of crystalline and of amorphous penicillin.

Procaine Penicillin.—Similarly, the concentrations of penicillin were determined in blood and tissue exudates after the intramuscular injection of procaine penicillin

TABLE I—PENICILLIN LEVELS IN BLOOD AND EXUDATE OF RABBITS AFTER INTRAMUSCULAR INJECTION OF 30,000 UNITS IN AQUEOUS SOLUTION

suspensions in oil. Six rabbits received 0·5 ml. of turpentine in the right hind leg; 48 hours later three of them were injected with 30,000 units of procaine penicillin, and the other three with 50,000 units, all in the left hind leg. Samples of blood and exudate were taken at intervals and assayed for the presence of penicillin. The results are shown in table III. In this experiment effective levels of penicillin were found in the exudate for at least 31 hours, whereas penicillin had disappeared from the blood in less than 24 hours.

Effect of Larger Doses.—Table IV records penicillin levels after the intramuscular injection of an aqueous solution of amorphous penicillin at three different doses. It seems that the largest dose of penicillin (100,000 units) did not much increase the time during which penicillin was found in the blood, but it produced higher penicillin levels in the exudate than did the smaller doses.

Distribution in Different Organs.—To determine the rate of distribution of penicillin in different organs and in the œdema fluid, six rabbits were injected intramuscularly with 0·6 ml. of turpentine; 24 hours later they were injected intramuscularly with 30,000 units of amorphous penicillin and killed, three 3 hours and three 5 hours later. At the time of killing, samples of blood and exudate from the damaged muscle were taken, and liver, lungs, spleen, normal muscle, and kidneys were removed. Weighed quantities were ground with sharp sand and transferred to 1 oz. bottles, 2 ml. of saline solution being added for each gramme of tissue. The bottles were shaken mechanically for 15 minutes and then left to stand at room temperature for 1½ hours. The penicillin was extracted with amyl acetate according to the method described by Florey et al. (1946). The penicillin was assayed by the serial dilution method in papain digest broth, *Staph. aureus* strain 663 being used as the test organism.

No detectable amounts of penicillin were found in any of the organs, except for traces in the kidney after 5 hours, but the exudate in the damaged muscle showed penicillin levels of 0·5–0·25 unit per ml. after 3 hours and 0·25–0·06 unit per ml. after 5 hours.

Penicillins F, G, and K.—The behaviour of the three penicillins F, G, and K was investigated. Groups of four rabbits, previously injected with turpentine, were injected intramuscularly with 30,000 units of the respective penicillins in aqueous solutions, and samples of blood and exudate were taken at regular intervals. The results (table V) confirm the known fact that penicillin G, and to a similar extent the mixture of penicillins F and dihydro F, give blood levels after intramuscular injection for about 2–3 hours, whereas penicillin K cannot be detected after 2 hours. The same relationship is found in the penicillin levels in the exudate after injection of the respective penicillins. Penicillin G can be detected up to 8 hours and the mixture of penicillins F and dihydro F up to 6 hours, but penicillin K only up to 2 hours.

DISCUSSION

Our observations support the findings of Florey et al. (1946) regarding the penicillin content of wounds. After single intramuscular injections penicillin levels are maintained much longer in the tissue exudate than in the blood. The results provide further justification for injecting penicillin in large doses at longer intervals. Adequate antibacterial levels of penicillin are maintained in the inflamed tissue for hours, despite its disappearance from the blood. Moreover, though no penicillin was detected in the organs of rabbits 3 or 5 hours after the injection of a single dose of penicillin, comparatively high levels were found in the inflamed tissue. Earlier experiments showed that the concentration of penicillin at the focus of inflammation is much higher in the first hour or two than in other tissues of the animal after a single injection of penicillin (Sorsby and Ungar 1946). This selective accumulation of penicillin in the inflamed area is one of the most important factors in the therapeutic effect of single massive doses of penicillin: it occurs with penicillins G, F, and K, and the therapeutic properties of the different penicillins are reflected in the levels of penicillin produced in the exudate by similar doses.

SUMMARY

The intramuscular injection of small amounts of turpentine into animals is a convenient method of obtaining frequent samples of sterile exudate.

After intramuscular injection of penicillin, detectable amounts remain in the fluid of damaged tissue for about twice as long as in the blood-stream.

The therapeutic effect of single massive doses of penicillin is partly explained by the prolonged accumulation of penicillin in the inflamed tissue.

My thanks are due to Dr. E. Lester Smith for preparing and supplying purified penicillins F, dihydro F, and K, and to Mr. P. W. Muggleton and Mr. B. I. Helliwell for their technical assistance.

ROYAL HOSPITAL FOR SICK CHILDREN, GLASGOW

THE following observations on tuberculous meningitis and its treatment with streptomycin are based on case-records made in the Royal Hospital for Sick Children, Glasgow, between January, 1947, and September, 1949. The number of children is small, but the period of observation is now 2½ years in some of the cases, so the results may be of interest to others working in the same field. The results at the end of 5 years may well be more gloomy than the present findings indicate, because of the unfavourable outcome in most of the children who relapse.

Between January, 1947, when the clinical trials of streptomycin in miliary and meningeal tuberculosis were instituted by the Medical Research Council, and September, 1949, thirty-three children have been given streptomycin treatment for tuberculous meningitis in this hospital. The present series includes only those children who were admitted to the hospital before the end of September, 1948, so the minimum observation period is 12 months.

DOSAGE

The dosage of streptomycin varied considerably. At the beginning of the trials very large doses were given both intramuscularly and intrathecally. The total intramuscular dosage was from 1 to 2 g. a day given 6-hourly. For several of the children this was truly heroic dosage; in one instance the allowance of streptomycin per lb. of body-weight was 70 mg. On this régime toxic effects on the kidneys—i.e., albuminuria, hæmaturia, and cylindruria—were encountered, all of which cleared readily when streptomycin was withheld. After the first few weeks the dosage of streptomycin by the intramuscular route was reduced, the total daily requirements being calculated on a basis of about 20 mg. per lb. of body-weight. This system was followed throughout the remainder of the series. A change was also made in the frequency of the intramuscular injections. It was found that equally satisfactory blood-streptomycin levels were obtained when injections were given twice daily as when they were given four times daily.

Experimental work on guineapigs has shown that the administration of streptomycin once or twice daily gives as good results as do 6-hourly injections (Feldman et al. 1947). Barnwell et al. (1947) consider that two injections daily, given 12-hourly, are just as effective as the earlier routine of more frequent administration and less inclined to damage the eighth cranial nerve.

At the outset of the trials relatively large amounts of streptomycin were also given intrathecally, the initial scheme being to inject a daily dose of 100 mg. dissolved in 5 ml. of physiological saline solution. Later the intrathecal dosage was reduced to 50 mg. daily for children over the age of 3 years, and 25 mg. daily for children under that age. The volume of each injection has varied between 5 and 10 ml. It is now generally agreed that larger intrathecal dosage is unnecessary and may even be harmful. The irritant effect of streptomycin on the theca is substantiated by the necropsy findings in case 1, a child who died after 22 days' treatment, during which streptomycin 100 mg. had been injected into the theca every day. The spinal cord was intensely congested, and the lumbar and thoracic leptomeninges were thickened.

ABSORPTION AND EXCRETION

The blood-streptomycin level reached its peak an hour after the intramuscular injection of half the total daily dose and fell gradually during the next 12 hours. At the end of 12 hours there was still 1–16 µg. of streptomycin per ml. of blood (fig. 1). Similar results were obtained by Cathie (1948) with 12-hourly injections.

Streptomycin is excreted chiefly by the kidneys; Corper and Cohn (1948) found that 41–86% was excreted in the urine in 12 hours; and the National Research Council (1946a) found that 60–80% of one injection appeared in the urine in 24 hours. No attempt was made in the present series to estimate the amount of streptomycin excreted in the urine after a single injection, but 24-hour collections of urine saved from some children receiving intramuscular streptomycin contained 320–3200 µg. per ml.

STREPTOMYCIN IN CEREBROSPINAL FLUID

After intramuscular injection streptomycin appears in the cerebrospinal fluid (C.S.F.) in small amounts if the meninges are normal, and in larger amounts if meningitis is present (Medical Research Council 1948). In the present series 8 µg. of streptomycin per ml. of C.S.F. was commonly found during the active stage of the meningitis at intervals of 1–4 hours after an intramuscular injection. In several children given only one intramuscular injection on the day of the estimation 1 µg. per ml. was detected at the end of 24 hours.

The relative impermeability of the meninges to streptomycin in the absence of meningitis was observed in two instances. Case 24, while being treated for miliary tuberculosis before the onset of her meningitis, had 0·5 µg. of streptomycin per ml. of C.S.F. 4 hours after the intramuscular injection. Case 11, who in the first few weeks responded very promptly to treatment for

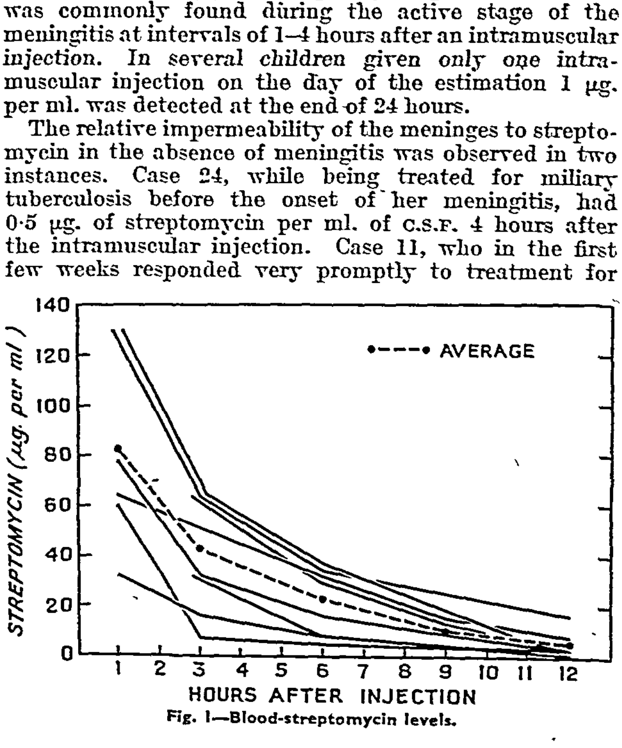

Fig. 1—Blood-streptomycin levels.

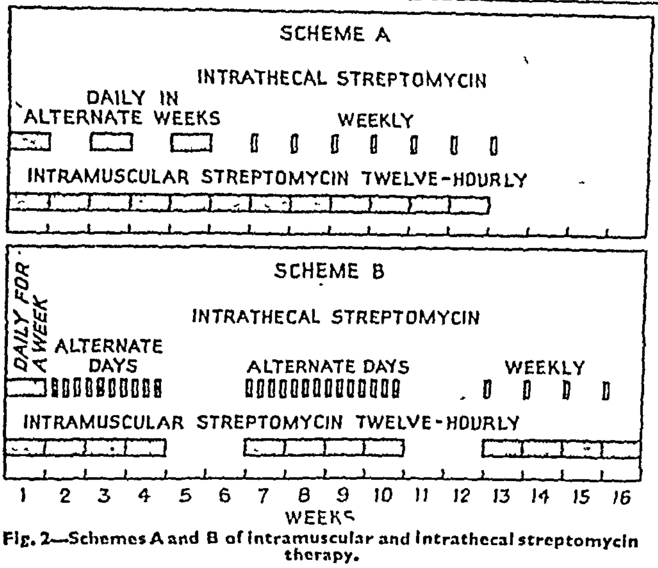

Fig. 2—Schemes A and B of intramuscular and intrathecal streptomycin therapy.

meningitis, thereafter never had more than 1 µg. of streptomycin per ml. of C.S.F. an hour after injection. It has been impossible to use the C.S.F.-streptomycin level as a prognostic index, as was suggested by the Medical Research Council (1948).

The length of time during which streptomycin remained in the C.S.F. after intrathecal injection was investigated in one child. Intramuscular treatment was stopped for 48 hours before the injection of 50 mg. intrathecally. The C.S.F. contained no streptomycin before the injection, 8 µg. per ml. 6 hours after injection, and no detectable concentration 12 and 24 hours after injection. No observations were made on the absorption of streptomycin into the blood-stream from the subarachnoid space.

SCHEDULES OF TREATMENT

At the beginning of the trials streptomycin was given for long periods, both intramuscularly and intrathecally, and temporarily stopped on the appearance of toxic effects. Later, however, two schemes of treatment were evolved (fig. 2)

Scheme A begins with an initial course of 12 weeks' continuous intramuscular treatment. During this period intrathecal injections are given daily during the first, third, and sometimes the fifth weeks of the schedule—i.e., on alternate weeks the child receives no intrathecal streptomycin. For the remainder of the period injections are given once weekly into the subarachnoid space. After the initial 12 weeks' course no further treatment is given unless indicated by the clinical condition or by a rising cell count in the C.S.F.

Scheme B consists of three or sometimes four separate periods of treatment, each lasting four weeks, with intervals of 14 days. Throughout each of these periods intramuscular treatment is given daily. During the first period intrathecal injections are given daily for the first week and on alternate days for the remainder of the period; during the second period the intrathecal injections are given on alternate days; and during subsequent periods they are given once weekly.

In both schedules of treatment intensive intrathecal treatment is given for a short period at the beginning of treatment and is followed by less frequent injections throughout the course. Experience suggests that long intensive intrathecal treatment is unnecessary. This conclusion is borne out particularly by case 11, who is normal mentally and physically, has a normal C.S.F. 25 months after the start of treatment and 19 months since her last intramuscular course, and received a total of 22 intrathecal injections—a short intensive course.

INTRAMUSCULAR STREPTOMYCIN ALONE

In five cases the tuberculous meningitis was treated with intramuscular streptomycin alone:

Case 12 completed a course of 1 g. daily for 150 days 24 months ago, and remained very well and without any evidence of active infection until 2 months ago, when he had a relapse of typical tuberculous meningitis, from which he is again making an excellent recovery, but this time with intrathecal as well as intramuscular streptomycin therapy. He suffered no toxic effects attributable to the streptomycin and showed no pathological sequelæ until his relapse.

Case 13 remained on intramuscular streptomycin and got steadily worse until death occurred after 49 days.

Case 16 received intrathecal streptomycin for only 2 days before death, after 41 days' unsuccessful intramuscular therapy.

In cases 15 and 18 intrathecal treatment was begun when 10 weeks' and 5 weeks' intramuscular therapy respectively had proved unsuccessful. Both children thereupon began to improve gradually as regards both mental and physical health, but case 18 had a relapse and died.

From this limited experience it is obvious that intramuscular streptomycin given alone is often inadequate for the treatment of tuberculous meningitis, a finding which is recorded by most other workers—e.g., Hinshaw et al. (1946) and the Medical Research Council (1948).

RESULTS

The results obtained in these thirty-three patients in the past 2½ years are recorded in table I. The figures indicating the duration of meningitis before the start of treatment are necessarily approximations, since it was not always possible to trace the precise day when the child became ill.

The assessment of the stage of the disease at the onset of treatment was based on the advice given by the Streptomycin in Tuberculous Meningitis Committee of the Department of Health for Scotland and was as follows:

Early: minimal physical signs; no neurological signs; no coma; not bad mental confusion.

TABLE I—TUBERCULOUS MENINGITIS TREATED WITH STREPTOMYCIN

O.T., still on treatment; B, complete block; Bp., partial and temporary block; E, early; I, intermediate; L, late; Dis., disabled; *, ventricular C.S.F.

Intermediate: definite physical signs; neurological signs resent; confusion but no deep coma.

Late: deep coma, patient barely able to be roused.

Mortality.—Of the thirty-three children eighteen are dead, ten alive and well, and five alive but disabled. Of the twenty-seven who completed treatment more han a year ago, sixteen are dead, eight alive and well, nd three alive but disabled. Of the twelve who have been observed for more than 2 years, six are dead, five alive and well, and one alive but disabled.

Of the eighteen patients who died five did not benefit rom treatment, and one of these (case 20) died on the second day of treatment. No constant feature was recognised in these five patients as foretelling their complete lack of response to treatment. The necropsy findings in some of these patients have been described by Montgomery (1948).

Disability.—Five of the fifteen survivors are seriously disabled: case 2 has a right hemiplegia, aphasia, mental defect, and occasional generalised convulsions; case 15 developed a right-sided hemiplegia concurrently with a relapse of meningitis but is improving slowly; case 25 is backward in development; case 23 was found, 5 weeks after the successful completion of treatment, to be developing hydrocephalus; and case 33, who has had three courses of streptomycin, and from whose C.S.F. positive cultures have been obtained before each course, now has moderate ataxia. Nine of the ten who are alive and well are living more or less normal lives in their own homes and have no clinically recognisable defects; the tenth went home, apparently well, in December, 1949.

Stage of Disease.—Though disappointment was experienced with some patients who seemed to be promising subjects for treatment but did not respond, nevertheless, when all the patients are grouped according to the stage of the disease at the onset of treatment, it is seen that the prognosis is much better in those who are seen early:

Stage at start of treatment	*No. of patients*	*Dead*	*Alive*
Early	10	4	6
Intermediate	20	11	9
Late	3	3	0

Age.—The influence of age is less striking in the present series than in the material collected by the Medical Research Council (1948). Our figures are as follows:

Age	*No. of patients*	*Dead*	*Alive*
All ages	33	18	15
Under 4 yr.	17	9	8
4 yr. and over	16	9	7

There is no appreciable difference in the group under the age of 4 years and those aged 4–12 years. Perhaps this is because the dividing line at 4 years is too high, and a better indication of the bad prognosis in the very young can be obtained if the division is made at 2 years. Of the seven children under the age of 2 years, five have died.

Tubercles of Choroid Plexus and Snowstorm Radiogram.—The patients have also been analysed as regards the presence or absence of tubercles of the choroid plexus and as regards the presence or absence of the typical radiographical mottling of the lung fields which is often likened to a snowstorm:

Tubercles of the Choroid Plexus

	Dead	*Alive*
Without choroidal tubercles	12	13
With choroidal tubercles	6	2

"Snowstorm" Radiograms of the Lungs

	Dead	*Alive*
Without "snowstorm" lung	11	13
With "snowstorm" lung	7	2

The mortality among patients showing either of these features is higher than among those not showing them. Included in the group with snowstorm lung are three children (cases 24, 30, and 33) whose case-records are of special interest.

TABLE II—RELAPSES OF TUBERCULOUS MENINGITIS

Case no.	Present condition	Week of treatment when relapse occurred	Interval since last treatment course (weeks)	Last C.S.F. taken before relapse			
				Cells (per c.mm.)	Protein (mg. per 100 ml.)	Chloride (mg. per 100 ml.)	Sugar (mg. per 100 ml.)
3	Dead	46	36	40	76	719	38
5	Dead	27	3	20	57	764	1
10	Well	12	5	130	59	695	25
12	Well	101	80	12	24	702	—
15	Disabled	61	36	9	58	650	51
26	Dead	18	5	13	90	674	20
33	Disabled	18	5	42	83	686	18

These children were admitted to the centre with miliary tuberculosis, and treatment with intramuscular streptomycin was begun. In none of them did routine lumbar puncture at the onset of therapy reveal any evidence of meningitis, which developed on about the 16th, 32nd, and 14th day of treatment respectively. In cases 30 and 33 the diagnosis of tuberculous meningitis was proved bacteriologically, the bacilli being found both on culture and on guineapig inoculation. In one of them bacilli were isolated when the C.S.F. was normal as regards cell count and content of protein, chloride, and sugar. Of these children, case 24 is very well, case 30 is dead, and case 33, who has had three courses of treatment, has been classed as disabled because of moderate ataxia, which is gradually improving.

C.S.F. Block.—A block in the flow of C.S.F. from the ventricles to the spinal subarachnoid space, and from the ventricles and basal cisterns to the absorption area over the cerebral hemispheres, undoubtedly interferes with the efficacy of treatment and is a serious added danger, but even a persistent spinal block does not preclude a satisfactory result.

Relapses.—One of the most disappointing features experienced by all workers using this form of therapy is the possibility of relapse in cases which had been expected to progress satisfactorily. A relapse of meningitis occurred in seven of our children, all of whom had been progressing favourably for at least a month before the deterioration was noted. The relapses took place after various intervals (see table II). In none had the C.S.F. returned to normal, but this fact is not of prognostic significance, since considerable variation has been found in the speed with which the constituents of the C.S.F. return to normal after the end of therapy. In three cases, however, the sugar content had been low in successive specimens of C.S.F. for some time before the relapse, and in one child the sugar level had fallen after having become normal. Therefore a low C.S.F.-sugar level may indicate cases liable to deteriorate clinically.

Conclusion.—So far as can be judged from the present series the prognosis is relatively good in patients with tuberculous meningitis treated with streptomycin when the patient is seen at an early stage of the disease, when he is over the age of 2 years, and when a snowstorm radiogram and choroidal tubercles are absent. Most of such patients should recover. If, on the other hand, the child is already very ill, under the age of 2 years, has had meningitis for more than 7 days, or has a snowstorm lung, choroidal tubercles, or a spinal or tentorial block, the prognosis is bad, and few such patients can be expected to benefit from streptomycin therapy.

BACTERIOLOGICAL FINDINGS

At the start of streptomycin therapy, in all cases, some bacteriological investigations were carried out as a routine. Specimens of C.S.F. were used for guineapig inoculation and culture. Further cultures were set up at weekly intervals throughout the course of treatment. During the first 7–14 days of treatment an intensive search was made for tubercle bacilli in the pellicles formed in the C.S.F. and in films of its centrifuged deposit. In addition, at least three specimens of gastric washings were examined microscopically, cultured, and used for guineapig inoculation. Sputum, when available, was submitted to careful scrutiny for acid-fast organisms.

The above-mentioned investigations were made in all the cases except case 20, who died on the day after admission—acid-fast bacilli had, however, been found in the pellicle formed in her C.S.F. In all the other cases tubercle bacilli were obtained as follows:

	Film or pellicle	*Culture*	*Guineapig inoculation*
C.S.F.	24	28	24
Gastric washings ..	4	6	12

Only in case 24 was there complete failure to obtain bacteriological proof in the C.S.F., whether by film, culture, or guineapig inoculation.

This girl had been in frequent contact with a relation who had open pulmonary tuberculosis, and was admitted to the centre in April, 1948, with a history of listlessness and loss of weight for the preceding 8 weeks. Her skin tests were strongly positive, and the chest radiogram showed the typical snowstorm lung of miliary tuberculosis. Treatment with intramuscular streptomycin was therefore begun. Meningitis developed about the 15th day of therapy, judged clinically by the onset of vomiting and nuchal rigidity accompanied by pleocytosis and increase of protein in the C.S.F.

With one exception (case 19) the infecting organism was of the human or eugonic type.

Resistance tests were carried out on all cases which yielded a positive culture within the first few weeks of treatment. The sensitivity of the infecting organisms to streptomycin was similar to that of the standard culture (the H37RV strain) and ranged from 0·125 µg. per ml. to 0·5 µg. per ml. In two cases only was an increase of resistance detected in a culture isolated after treatment, but this was so slight as to be insignificant. Unfortunately it has been impossible to form any conclusion about the development of resistance in the seven cases in which there was a relapse. Positive cultures were obtained after the relapse or at necropsy in only three cases out of the seven, and in one of these the growth was so poor that the organisms tended to die out on subculture. In another child, however, two positive cultures (one from the C.S.F. before death, and one from a caseous gland post mortem) were found to be no more streptomycin-resistant than was the original culture isolated at the beginning of treatment. It is now widely recognised that tubercle bacilli very seldom develop resistance to streptomycin during treatment of tuberculous meningitis. Among the cases cited in the report of the Medical Research Council (1948), however, are three which developed resistant strains during treatment (two of them were not inhibited by a concentration of 1000 µg. of streptomycin per ml.). All these patients had miliary tuberculosis, and all died. Another instance in tuberculous meningitis is cited by Youmans and Karlson (1947), who record that in the course of 48 days' treatment the streptomycin sensitivity rose from 0·78 µg. to 500 µg. per ml.

The number of positive C.S.F. cultures obtained in each case varied from none to 7 in two cases and 13 in one. The results show that the cases with numerous positive cultures are those with a poor prognosis:

No. of positive cultures	*Cases* *Total*	*Deaths*
Not more than 1	15	5
Not more than 2	20	8
More than 2	12	8

Three children from whom 4 positive cultures were isolated are still alive and well (cases 9, 15, and 22). No patient whose C.S.F. yielded more than 4 positive cultures has survived.

The adverse effect exerted on prognosis by the number of positive cultures is also described by the Medical Research Council (1948), which states that the frequency of positive cultures was much lower among the patients making good progress than among those who died.

RADIOLOGY

In this series the study of changes in the lungs was subsidiary to the treatment of the meningitis, and the following observations have therefore been very briefly recorded. They were made by one of us, who reviewed all the available plates of each patient, knowing the order in which they were taken, and assessed the material as accurately as he could. Plates were taken at intervals of not more than four weeks, except when they were required weekly. Case 20, who died within 2 days of starting treatment is omitted from the present discussion. Her radiogram showed the snowstorm lung of miliary tuberculosis.

Of the thirty-two cases being considered, all showed appreciable enlargement of the hilar shadows, which did not regress throughout the period of observation. Similarly, no change was noted in the appearance of the calcified primary foci present in three cases.

In two children presenting with enlargement of the hilar shadows only, some extension of the disease was noted. In one of these children the right lower lobe collapsed after 10 months' treatment and re-expanded again within a month. In the other child the hilar shadows were somewhat broader after 16 months' observation.

In addition to broadening of the hilar shadows, certain other features were noted in sixteen of the children. Eight showed the snowstorm radiogram characteristic of gross miliary tuberculosis. This group revealed during treatment not only the most striking radiological improvement but also the most uniform clinical deterioration of this series. In one case there was no change in the radiographical appearance during 2 months' observation, whereas the other seven cases showed complete or almost complete clearing of shadows in 1–9 months. However, six of the patients have died, and two, observed 12 and 17 months, are still alive.

In another group, comprising seven children, the initial lesion consisted of an absorption collapse of part or whole of a lobe in addition to hilar adenitis. In three of these no change occurred during observation periods of 3 months for two and 1 month for the third. Of the remaining four, three showed complete and one partial expansion, all occurring within 2 weeks to 4 months of the start of treatment.

In one child radiological examination on admission showed a glandular mass in the right lower zone, with emphysema of the right lower lobe. During the period of observation he twice developed collapse. On one occasion this resolved spontaneously; on the second occasion bronchoscopy, with aspiration of caseous material, was followed by re-expansion.

These observations suggest that streptomycin exerts little or no effect on the course of the primary tuberculous complex in children, and that, though it has a striking influence on the radiogram of snowstorm lung, this influence is seldom sufficient to ensure the child's survival.

COMPLICATIONS AND TOXIC EFFECTS

Only brief reference is made here to the various aspects of streptomycin toxicity, since this subject has already been described in detail (National Research Council 1946b, Farrington et al. 1947, McDermott 1947, Madigan et al. 1947, Fowler and Seligman 1947, Council on Pharmacy and Chemistry 1947).

Most of the patients on streptomycin treatment showed some degree of drug fever, the duration varying considerably from case to case. Intrathecal injections caused greater pyrexia than did intramuscular. Recurrent vomiting occurred in fifteen patients, in ten of whom was associated with increased intracranial pressure, ereas in the remaining five it appeared to be due rectly to the streptomycin.

Evidence of renal damage was often detected in the rly cases receiving large doses of streptomycin but ldom after the adoption of the lower dosage already scribed. The signs of renal impairment were albuminia, with casts, red cells, and white cells. When reptomycin was withheld, these signs disappeared.

Sensitisation rashes developed in eight children; ey were morbilliform or maculopapular and were always neralised and not itchy. The effect of anti-histamine ugs was tried on four occasions with unsatisfactory sults. In one case the rash was accompanied by gioneurotic œdema of the face and urticaria of the unk and limbs. After the injections of streptomycin d been stopped, these rashes usually disappeared ithin 1–4 days. Eosinophilia of more than 5% was etected in five patients and was not associated with sensitisation rash.

The eighth nerve was affected in fourteen children. estibular dysfunction was more common than impairent of hearing, the latter occurring in three patients nly. Gross tremor occurred in ten cases, ataxia involvg the whole body in six cases, and circular nystagmus four. These phenomena have disappeared comletely in all the children who survive. Nerve deafness as noted in three patients, two of whom became stone eaf and remained so until death, whereas the third has hown some improvement though there is still a noticeable mpairment of hearing.

Local reactions to the intramuscular injection of treptomycin have proved of little significance. The hildren sometimes complained of pain at the site for ne or two hours, and in six cases red swollen tender nodes ppeared, which yielded to simple treatment. The reparation of the drug now used—streptomycin calcium hloride complex—does not seem to differ from the other alts—hydrochloride and sulphate—as regards pain n injection. Intrathecal injections may be painful if the olution used is cold, or after long-continued therapy hen adhesions have formed and referred pain in the egs and back may be caused by pressure and stretching f the nerve-roots. Intraventricular injections, on the ther hand, caused no pain and minimal inflammation n the C.S.F. Injections into the subarachnoid space nay produce considerable inflammation round the ord at the site of injection.

The development of blindness and of thromboses of erebral vessels leading to hemiplegia, &c., is probably lue mainly to the meningitis and not a toxic effect of treptomycin.

Obstruction to the flow of C.S.F. in the subarachnoid pace is an important complication of streptomycin herapy, and will be discussed more fully later. Eight hildren of the present series developed spinal block, which was only partial in two cases. Three children had a tentorial block, and two of these had also a spinal block. Both complications necessitate the making of cranial burr-holes through which the streptomycin can be injected into the ventricle, thus ensuring a more adequate circulation through the subarachnoid space and, in the event of tentorial block, reducing the C.S.F. pressure within the ventricular system.

DISCUSSION

Though the series is small and the follow-up brief, certain conclusions may be drawn.

The prognosis is relatively favourable where the meningitis is of short duration, the patient's clinical condition is good, he is over the age of 2 years, and he has no snowstorm radiogram, choroidal tubercles, or spinal or tentorial block. The converse of any of these conditions makes the prognosis bad. This fact emphasises once again the vital importance of early diagnosis and prompt institution of intramuscular and intrathecal streptomycin therapy if a larger proportion of children with tuberculous meningitis are to survive.

In the diagnosis chemical analysis of the C.S.F. is most important for differentiating serous from caseous tuberculous meningitis (Lincoln 1947); but, though the serous type has a better prognosis than has the classical caseous type, streptomycin therapy should be instituted in both types.

Continuing study of antibiotic agents and of the synergism between certain chemotherapeutic substances and antibiotics may well lead to the evolution of a much more effective means of treating miliary and meningeal tuberculosis, but for the time being most investigations are concerned with the technique of treatment and the prevention of complications. It is generally agreed that a total daily dosage of about 20 mg. of streptomycin base per lb. of body-weight provides a satisfactory basis for the treatment of children, and 12-hourly intramuscular injections seem as effective as 6-hourly or 4-hourly injections. The treatment should continue for 3–6 months, with or without short intermissions. Intrathecal injections should not exceed 50 mg., but the best frequency and number of these is not yet established.

Many efforts have been made to prevent the development of a block in the circulation of the C.S.F. The various mechanical devices investigated by Smith et al. (1948) have not led to any great improvement in results, though they have done much to clarify the mechanism whereby these disasters occur. Cathie (1949) has introduced a streptococcal fibrinolysin, which has shown promising effects in preliminary clinical trials.

Finally, it is claimed that in spite of lack of response of some cases to treatment when circumstances seem propitious, it is possible in many instances to make a reasonably accurate forecast of the immediate outcome of any individual case of tuberculous meningitis. Unfortunately the eventual fate of those who survive is more uncertain, and constitutes a problem of considerable sociological importance, when it is realised that about a third of the survivors are left with serious permanent sequelæ.

SUMMARY

The systems of treatment with streptomycin for tuberculous meningitis now in force in this hospital are described and the results obtained in the treatment of thirty-three children are recorded and analysed. The period of observation of these children varied from 32 to 12 months. When treatment is started early and there are no complicating factors most of the patients recover.

We wish to thank Prof. G. B. Fleming, Prof. Stanley Graham, and Dr. James H. Hutchison for access to the case-records and for advice in the preparation of this paper; and the staff of the biochemistry, pathology, and radiology departments for their arduous investigations.

INFLUENZA IN AN ISOLATED COMMUNITY

AN EPIDEMIC ON OCEAN ISLAND

MEDICAL OFFICER, OCEAN ISLAND

Ocean Island is a British Colony in the Gilbert group of islands, situated about 3000 miles north-east of Melbourne. Most of the island is given over to phosphate mining. The British Phosphate Company employs either native labourers transported from the neighbouring Gilbert and Ellice Isles in groups of 100–800 or Chinese labour imported from Hong-Kong. Usually labourers are kept on the island for 6–18 months and then replaced.

It is well known to some of the lay members of the phosphate company's permanent staff on the island that after the arrival of Chinese labourers severe influenza is liable to break out among the native Gilbert and Ellice Islanders. Thus, in 1930 Chinese labourers arrived on Ocean Island in March and September. The incidence of cases of clinical influenza in 1930 was as follows: April 444, May 92, June 57, July 186, October 648, November 144. The racial incidence of these outbreaks has been characteristic; natives who have presumably had no previous contact with influenza have shown an almost 100% incidence, whereas Chinese or whites have shown either a low incidence or an absence of clinical infections.

These unusual features have prompted an investigation into an epidemic which occurred in October, 1948, and followed the characteristic pattern of previous outbreaks. Clinical examination of the cases on the island was combined with investigation of garglings and sera from some of the cases and contacts.

EPIDEMIOLOGY

In September, 1947, 800 fresh Gilbert and 300 Ellice Islanders arrived on Ocean Island. In June, 1948, most of these were repatriated except for 290 Ellice Islanders and 10 Gilbertese. Until the present outbreak there was no significant disease among the natives on the island. They were housed in huts 16 ft. by 8 ft. with a partition down the middle, four men to each hut. The huts are all situated together in a compound covering several acres.

On Oct. 3, 1948, a ship arrived from Hong-Kong with 803 Chinese labourers aboard. The journey from Hong-Kong had taken 3 weeks, conditions of overcrowding were bad, and coughs were prevalent, but there had been no clinical influenza. On arrival the Chinese were admitted to quarantine, from which they were released 24 hours later after examination by the island medical officer. They were housed in two compounds similar to the native compound and about half a mile away. There was ample opportunity for contact between natives and Chinese at work.

On Oct. 13, a ship arrived from Australia with 10 European passengers and an Indian crew. The natives of the island had contact with the Indians, but there was not even minor sickness among the crew. On the same day the first case of upper respiratory tract infection was admitted to hospital; 271 cases were admitted in the next fortnight. The daily case-incidence as judged by hospital admissions is shown in the accompanying figure.

The racial incidence was particularly interesting. Not one Chinese was admitted to hospital; but 12 Europeans were admitted out of about 90 on the island. The few Gilbertese were not seriously affected, but the incidence among Ellice Islanders was exceptionally high. Among these, almost all the men, about half the women, and 10% of the children on the island became ill.

CLINICAL FEATURES

The onset was usually sudden, with a rigor as the most common presenting symptom. Temperatures were high —103–105°F—and the patients often complained of feeling faint. Pain in the back and limbs and sore eyes were common, and there was usually an irritating unproductive cough.

Out of 271 admissions the average stay in hospital was 9·4 days, with a minimum of 2 days and a maximum of 35 days. There were five deaths—on the 9th, 10th, 12th, 13th, and 26th days of illness—the fatal cases showing jaundice. Necropsies could not be done.

ISOLATION OF VIRUS

Garglings were collected on Oct. 17 from 12 cases with a temperature higher than 101°F and within 36 hours of the onset of symptoms. Patients were asked to gargle with 10 ml. of sterile saline solution, and the washings were mixed with an equal volume of 10% serum-broth and stored in the refrigerator until they could be transferred to the cool room of a ship sailing for Australia. The garglings took 5 weeks to reach the laboratory. On arrival they were inoculated amniotically into 13-day-old chick embryos by the method of Burnet (1940); penicillin and sodium sulphadiazine were added to the inoculum to reduce bacterial growth. Sera were collected from the patients at the same time as the garglings were taken and again two weeks later, during convalescence. In the laboratory the sera were examined for their anti-hæmagglutinin content by a modification (Burnet 1942) of the method of Hirst (1942).

Influenza virus was isolated from ten out of twelve garglings. The virus was present in the O phase (Burnet and Bull 1943)—i.e., infected fluids agglutinated guinea-

MEDICAL OFFICER, OCEAN ISLAND

Ocean Island is a British Colony in the Gilbert group of islands, situated about 3000 miles north-east of Melbourne. Most of the island is given over to phosphate mining. The British Phosphate Company employs either native labourers transported from the neighbouring Gilbert and Ellice Isles in groups of 100–800 or Chinese labour imported from Hong-Kong. Usually labourers are kept on the island for 6–18 months and then replaced.

It is well known to some of the lay members of the phosphate company's permanent staff on the island that after the arrival of Chinese labourers severe influenza is liable to break out among the native Gilbert and Ellice Islanders. Thus, in 1930 Chinese labourers arrived on Ocean Island in March and September. The incidence of cases of clinical influenza in 1930 was as follows: April 444, May 92, June 57, July 186, October 648, November 144. The racial incidence of these outbreaks has been characteristic; natives who have presumably had no previous contact with influenza have shown an almost 100% incidence, whereas Chinese or whites have shown either a low incidence or an absence of clinical infections.

These unusual features have prompted an investigation into an epidemic which occurred in October, 1948, and followed the characteristic pattern of previous outbreaks. Clinical examination of the cases on the island was combined with investigation of garglings and sera from some of the cases and contacts.

EPIDEMIOLOGY

In September, 1947, 800 fresh Gilbert and 300 Ellice Islanders arrived on Ocean Island. In June, 1948, most of these were repatriated except for 290 Ellice Islanders and 10 Gilbertese. Until the present outbreak there was no significant disease among the natives on the island. They were housed in huts 16 ft. by 8 ft. with a partition down the middle, four men to each hut. The huts are all situated together in a compound covering several acres.

On Oct. 3, 1948, a ship arrived from Hong-Kong with 803 Chinese labourers aboard. The journey from Hong-Kong had taken 3 weeks, conditions of overcrowding were bad, and coughs were prevalent, but ther been no clinical influenza. On arrival the Chines admitted to quarantine, from which they were re 24 hours later after examination by the island m officer. They were housed in two compounds simi the native compound and about half a mile away. was ample opportunity for contact between native Chinese at work.

On Oct. 13, a ship arrived from Australia wi European passengers and an Indian crew. The nati the island had contact with the Indians, but ther not even minor sickness among the crew. On the day the first case of upper respiratory tract infe was admitted to hospital; 271 cases were admitt the next fortnight. The daily case-incidence as ju by hospital admissions is shown in the accompar figure.

The racial incidence was particularly interesting. one Chinese was admitted to hospital; but 12 Europ were admitted out of about 90 on the island. The Gilbertese were not seriously affected, but the incid among Ellice Islanders was exceptionally high. An these, almost all the men, about half the women, 10% of the children on the island became ill.

CLINICAL FEATURES

The onset was usually sudden, with a rigor as the common presenting symptom. Temperatures were —103–105°F—and the patients often complaine feeling faint. Pain in the back and limbs and sore were common, and there was usually an irrita unproductive cough.

Out of 271 admissions the average stay in hospital 9·4 days, with a minimum of 2 days and a maximu 35 days. There were five deaths—on the 9th, 10th, 1 13th, and 26th days of illness—the fatal cases sho jaundice. Necropsies could not be done.

ISOLATION OF VIRUS

Garglings were collected on Oct. 17 from 12 cases a temperature higher than 101°F and within 36 hou the onset of symptoms. Patients were asked to ga with 10 ml. of sterile saline solution, and the wash were mixed with an equal volume of 10% serum-b and stored in the refrigerator until they could be tr ferred to the cool room of a ship sailing for Austr The garglings took 5 weeks to reach the laboratory. arrival they were inoculated amniotically into 13-day- chick embryos by the method of Burnet (1940); penici and sodium sulphadiazine were added to the inocul to reduce bacterial growth. Sera were collected from patients at the same time as the garglings were ta and again two weeks later, during convalescence. the laboratory the sera were examined for their a hæmagglutinin content by a modification (Burnet 19 of the method of Hirst (1942).

Influenza virus was isolated from ten out of twe garglings. The virus was present in the O phase (Bur and Bull 1943)—i.e., infected fluids agglutinated guin

MEDICAL OFFICER, OCEAN ISLAND

Ocean Island is a British Colony in the Gilbert group of islands, situated about 3000 miles north-east of Melbourne. Most of the island is given over to phosphate mining. The British Phosphate Company employs either native labourers transported from the neighbouring Gilbert and Ellice Isles in groups of 100–800 or Chinese labour imported from Hong-Kong. Usually labourers are kept on the island for 6–18 months and then replaced.

It is well known to some of the lay members of the phosphate company's permanent staff on the island that after the arrival of Chinese labourers severe influenza is liable to break out among the native Gilbert and Ellice Islanders. Thus, in 1930 Chinese labourers arrived on Ocean Island in March and September. The incidence of cases of clinical influenza in 1930 was as follows: April 444, May 92, June 57, July 186, October 648, November 144. The racial incidence of these outbreaks has been characteristic; natives who have presumably had no previous contact with influenza have shown an almost 100% incidence, whereas Chinese or whites have shown either a low incidence or an absence of clinical infections.

These unusual features have prompted an investigation into an epidemic which occurred in October, 1948, and followed the characteristic pattern of previous outbreaks. Clinical examination of the cases on the island was combined with investigation of garglings and sera from some of the cases and contacts.

EPIDEMIOLOGY

In September, 1947, 800 fresh Gilbert and 300 Ellice Islanders arrived on Ocean Island. In June, 1948, most of these were repatriated except for 290 Ellice Islanders and 10 Gilbertese. Until the present outbreak there was no significant disease among the natives on the island. They were housed in huts 16 ft. by 8 ft. with a partition down the middle, four men to each hut. The huts are all situated together in a compound covering several acres.

On Oct. 3, 1948, a ship arrived from Hong-Kong with 803 Chinese labourers aboard. The journey from Hong-Kong had taken 3 weeks, conditions of overcrowding were bad, and coughs were prevalent, but there had been no clinical influenza. On arrival the Chinese were admitted to quarantine, from which they were released 24 hours later after examination by the island medical officer. They were housed in two compounds similar to the native compound and about half a mile away. There was ample opportunity for contact between natives and Chinese at work.

On Oct. 13, a ship arrived from Australia with 10 European passengers and an Indian crew. The natives of the island had contact with the Indians, but there was not even minor sickness among the crew. On the same day the first case of upper respiratory tract infection was admitted to hospital; 271 cases were admitted in the next fortnight. The daily case-incidence as judged by hospital admissions is shown in the accompanying figure.

The racial incidence was particularly interesting. Not one Chinese was admitted to hospital; but 12 Europeans were admitted out of about 90 on the island. The few Gilbertese were not seriously affected, but the incidence among Ellice Islanders was exceptionally high. Among these, almost all the men, about half the women, and 10% of the children on the island became ill.

CLINICAL FEATURES

The onset was usually sudden, with a rigor as the most common presenting symptom. Temperatures were high —103–105°F—and the patients often complained of feeling faint. Pain in the back and limbs and sore eyes were common, and there was usually an irritating unproductive cough.

Out of 271 admissions the average stay in hospital was 9·4 days, with a minimum of 2 days and a maximum of 35 days. There were five deaths—on the 9th, 10th, 12th, 13th, and 26th days of illness—the fatal cases showing jaundice. Necropsies could not be done.

ISOLATION OF VIRUS

Garglings were collected on Oct. 17 from 12 cases with a temperature higher than 101°F and within 36 hours of the onset of symptoms. Patients were asked to gargle with 10 ml. of sterile saline solution, and the washings were mixed with an equal volume of 10% serum-broth and stored in the refrigerator until they could be transferred to the cool room of a ship sailing for Australia. The garglings took 5 weeks to reach the laboratory. On arrival they were inoculated amniotically into 13-day-old chick embryos by the method of Burnet (1940); penicillin and sodium sulphadiazine were added to the inoculum to reduce bacterial growth. Sera were collected from the patients at the same time as the garglings were taken and again two weeks later, during convalescence. In the laboratory the sera were examined for their anti-hæmagglutinin content by a modification (Burnet 1942) of the method of Hirst (1942).

Influenza virus was isolated from ten out of twelve garglings. The virus was present in the O phase (Burnet and Bull 1943)—i.e., infected fluids agglutinated guinea-

pig and human cells to relatively high titre but did not agglutinate fowl cells. Serological investigation showed that the virus was an influenza type A strain. Table I shows the anti-hæmagglutinin titres of pairs of acute and convalescent sera of six patients from the present epidemic tested against six laboratory strains of influenza A and a strain of swine-influenza virus.

Dried allantoic fluid of a strain of Ocean Island virus was sent to the World Influenza Centre (W.H.O.), Hampstead, London, where the virus was examined with the electron microscope. Chu et al. (1949) have reported that recently isolated strains of influenza virus A, including the Ocean Island strain, showed numerous elongated forms, unlike previously isolated strains, where these forms were uncommon. Dr. C. H. Andrewes (personal communication) has suggested that long forms could be seen with dark-ground illumination in an ordinary microscope. By this means it was found that Ocean Island virus and strains CAM, FJS, and FMI (see table I), unlike strains BEL and MEL, showed numerous long forms. These results provide evidence of morphological and serological similarity among recently isolated strains.

At the same time as the convalescent sera were taken, single specimens of serum were collected from 12 Chinese. The Chinese and Ellice Islanders' sera were tested for complement-fixing antibody to influenza viruses A and B by the method of Donnelley (1950). The results are shown in table II. It can be seen that the Ellice Islanders' sera showed a reaction diagnostic of infection with influenza virus A, and a negative reaction to influenza B. Moderately high titres of complement-fixing antibody to influenza A were also found in most of the Chinese sera. With the technique used these titres strongly suggest recent infection with influenza virus A.

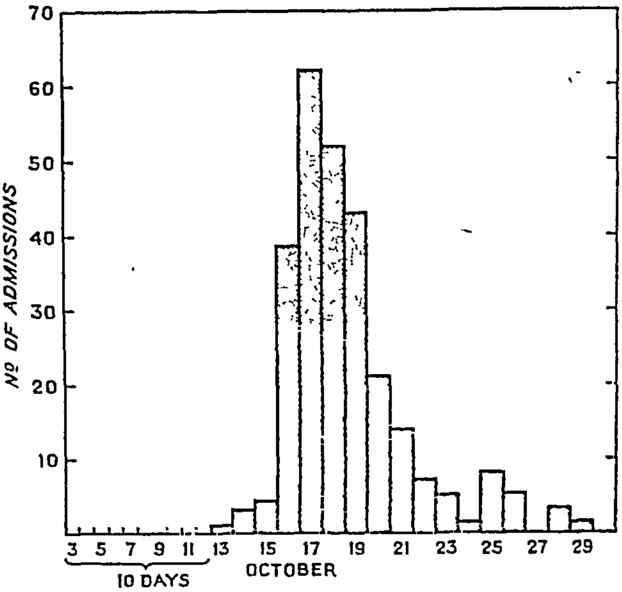
DISCUSSION

An interesting aspect of the epidemic is the difference in the response of whites, Chinese, and Ellice Islanders to the same infecting agent. At the time of the epidemic the white population showed a 15% incidence of clinical influenza. This does not differ greatly from that shown in other countries during the last 2 years to infection with a serologically identical strain of influenza virus A. The Chinese showed no clinical disease, though there was serological evidence of recent infection with influenza virus A. So far as the Ellice Islanders were concerned, the Ocean Island outbreak was typical of a "virgin soil" epidemic in its high case-incidence. In agreement with this none of the sera showed any evidence of complement-fixing antibody at the time of onset of symptoms.



Daily case-incidence.

All acute-stage sera tested gave a high non-specific titre against the homologous strain in the anti-hæmagglutination test; most of the convalescent sera showed a "broad" anti-hæmagglutinin response. None showed the specific type of response observed by Anderson (1947) in a proportion of sera from adolescents in a recent Melbourne outbreak of influenza A. An interesting point is that none gave any significant anti-hæmagglutinin response to a strain of swine virus. In 1933–42 most convalescent sera from influenza-A cases showed a sharp rise in titre with this strain. It seems likely that the more recent strains are more "distant" serologically from swine than were those of the earlier period.

The part played by the Chinese in this epidemic is particularly noteworthy. The epidemiological data taken with the account of the island's past experience are consistent with the view that the infection was introduced with the shipload of Chinese labourers who were released from quarantine 9 days before the first case was admitted to hospital. No Chinese were admitted to hospital during the epidemic, indicating a high level of resistance to clinical infection. The sera taken from a random group of Chinese 3–4 weeks after the start of the epidemic nearly all showed a moderately high complement-fixing antibody titre against A antigen but none against B. In the absence of any clinical influenza on the voyage from China we are strongly inclined to view this as evidence of subclinical infection by A virus during the island epidemic. If it represented merely evidence of fairly recent casual infection in China or on the voyage we should have expected fewer positive A titres and a more or less similar proportion of reactions with the B antigen. One of the outstanding problems in influenza is to know why some people become infected, excrete virus (Crowley et al. 1944), and develop anti-hæmagglutinin and/or complement-fixing antibody without showing clinical symptoms. If our interpretation is correct, a striking example of this phenomenon involving almost all the Chinese occurred on Ocean Island.

Epidemics have appeared on this island in the past almost as predicted. This would provide an excellent opportunity for studying the effect of immunisation in a population highly sensitive to influenza infection.

Ocean Island is a British Colony in the Gilbert group of islands, situated about 3000 miles north-east of Melbourne. Most of the island is given over to phosphate mining. The British Phosphate Company employs either native labourers transported from the neighbouring Gilbert and Ellice Isles in groups of 100–800 or Chinese labour imported from Hong-Kong. Usually labourers are kept on the island for 6–18 months and then replaced.

It is well known to some of the lay members of the phosphate company's permanent staff on the island that after the arrival of Chinese labourers severe influenza is liable to break out among the native Gilbert and Ellice Islanders. Thus, in 1930 Chinese labourers arrived on Ocean Island in March and September. The incidence of cases of clinical influenza in 1930 was as follows: April 444, May 92, June 57, July 186, October 648, November 144. The racial incidence of these outbreaks has been characteristic; natives who have presumably had no previous contact with influenza have shown an almost 100% incidence, whereas Chinese or whites have shown either a low incidence or an absence of clinical infections.

These unusual features have prompted an investigation into an epidemic which occurred in October, 1948, and followed the characteristic pattern of previous outbreaks. Clinical examination of the cases on the island was combined with investigation of garglings and sera from some of the cases and contacts.

EPIDEMIOLOGY

In September, 1947, 800 fresh Gilbert and 300 Ellice Islanders arrived on Ocean Island. In June, 1948, most of these were repatriated except for 290 Ellice Islanders and 10 Gilbertese. Until the present outbreak there was no significant disease among the natives on the island. They were housed in huts 16 ft. by 8 ft. with a partition down the middle, four men to each hut. The huts are all situated together in a compound covering several acres.

On Oct. 3, 1948, a ship arrived from Hong-Kong with 803 Chinese labourers aboard. The journey from Hong-Kong had taken 3 weeks, conditions of overcrowding were bad, and coughs were prevalent, but there had been no clinical influenza. On arrival the Chinese were admitted to quarantine, from which they were released 24 hours later after examination by the island medical officer. They were housed in two compounds similar to the native compound and about half a mile away. There was ample opportunity for contact between natives and Chinese at work.

On Oct. 13, a ship arrived from Australia with 10 European passengers and an Indian crew. The natives of the island had contact with the Indians, but there was not even minor sickness among the crew. On the same day the first case of upper respiratory tract infection was admitted to hospital; 271 cases were admitted in the next fortnight. The daily case-incidence as judged by hospital admissions is shown in the accompanying figure.

The racial incidence was particularly interesting. Not one Chinese was admitted to hospital; but 12 Europeans were admitted out of about 90 on the island. The few Gilbertese were not seriously affected, but the incidence among Ellice Islanders was exceptionally high. Among these, almost all the men, about half the women, and 10% of the children on the island became ill.

CLINICAL FEATURES

The onset was usually sudden, with a rigor as the most common presenting symptom. Temperatures were high —103–105°F—and the patients often complained of feeling faint. Pain in the back and limbs and sore eyes were common, and there was usually an irritating unproductive cough.

Out of 271 admissions the average stay in hospital was 9·4 days, with a minimum of 2 days and a maximum of 35 days. There were five deaths—on the 9th, 10th, 12th, 13th, and 26th days of illness—the fatal cases showing jaundice. Necropsies could not be done.

ISOLATION OF VIRUS

Garglings were collected on Oct. 17 from 12 cases with a temperature higher than 101°F and within 36 hours of the onset of symptoms. Patients were asked to gargle with 10 ml. of sterile saline solution, and the washings were mixed with an equal volume of 10% serum-broth and stored in the refrigerator until they could be transferred to the cool room of a ship sailing for Australia. The garglings took 5 weeks to reach the laboratory. On arrival they were inoculated amniotically into 13-day-old chick embryos by the method of Burnet (1940); penicillin and sodium sulphadiazine were added to the inoculum to reduce bacterial growth. Sera were collected from the patients at the same time as the garglings were taken and again two weeks later, during convalescence. In the laboratory the sera were examined for their anti-hæmagglutinin content by a modification (Burnet 1942) of the method of Hirst (1942).

Influenza virus was isolated from ten out of twelve garglings. The virus was present in the O phase (Burnet and Bull 1943)—i.e., infected fluids agglutinated guinea-

SUMMARY

Epidemics of influenza are known to develop in Ocean Island soon after the periodic arrivals of Chinese labourers from Hong-Kong.

An epidemic of influenza A in the island in 1948 was studied clinically and bacteriologically.

The incidence of clinical cases was about 15% among whites, and almost 100% in native Ellice Islanders, but no clinical cases appeared among the 800 Chinese.

Serological evidence suggests that there was a high incidence of subclinical infection in the Chinese.

The island would provide suitable material for testing the effects of immunisation against influenza.

We wish to thank Prof. F. M. Burnet, F.R.S., for his advice and criticism, and the British Phosphate Co. for their collaboration.

PEMPHIGUS VULGARIS TREATED WITH AUREOMYCIN

F. RAY BETTLEY
M.D. Lond., F.R.C.P.
DERMATOLOGIST TO THE MIDDLESEX HOSPITAL

THE curative treatment of pemphigus vulgaris has been so unsatisfactory that it is inevitable that new remedies, particularly antibiotics, will constantly be tried. In the following case 'Aureomycin' appeared to be effective.

CASE-REPORT

A middle-aged woman of German Jewish origin, whom I first saw on Sept. 5, 1949, then complained of sores inside the mouth since about the beginning of July, followed a month later by blisters and sores on the trunk. At that time there were very many superficial erosions on the mucous membrane of the cheeks, gums, and lips. A few scattered blisters up to $1^1/_2$ inches in diameter were to be seen on the back of the trunk, together with a few groups of smaller vesicles. The clinical diagnosis was pemphigus vulgaris; hospital admission was refused, and liquor arsenicalis, 3 minims t.d.s. by mouth, was started.

The patient's condition deteriorated considerably, and on Sept. 20 she was admitted to hospital. The clinical picture of pemphigus vulgaris was then well developed. Blisters, and the sores resulting from them, covered a large part of the trunk, scalp, thighs, and legs. There was also a purulent paronychia of staphylococcal type; for this reason, more than because of the pemphigus, procaine penicillin was given. A week's treatment (450,000 units twice daily) was without apparent effect on the pemphigus, fresh lesions of which were appearing every day. For the next week suramin was given intravenously every other day, also without effect on the pemphigus. Local treatment consisted of the application of penicillin cream when secondary sepsis was prominent, and anæsthetic ointments at other times. 'Nestosyl,' benzocaine ointment, and 'Anthisan' cream were found to relieve pain from the skin.

During the first fortnight of October the patient's general condition became steadily worse. Her temperature slowly rose from an average of 99°F to the region of 100–102°, heavy sedation was necessary because of pain, and this, together with the sores in the mouth, reduced her consumption of food to almost nothing.

On Oct. 13 aureomycin was started by mouth, 250 mg. being given on the first day; 250 mg. twice daily on the second day; 250 mg. four times on the third day; and thereafter 500 mg. six-hourly (four doses per day, total 2 g. daily). Within twenty-four hours of starting this treatment the improvement in the patient's general condition was very striking. Her temperature started to go down and, though it afterwards fluctuated, it reached normal on the third day of aureomycin treatment. No fresh blisters appeared after aureomycin was started, nor have there been any subsequently.

Aureomycin was continued at the same dosage until Nov. 25. During the six weeks' period of its administration there were two short breaks owing to difficulty in obtaining supplies, and occasional doses were omitted because of nausea. This was a prominent symptom; no doubt it can partly be attributed to heavy sedation, but the patient's appetite improved so strikingly within a few hours of stopping aureomycin that most of the nausea and anorexia must be blamed on the antibiotic. Throughout the period of treatment, up to the time of her discharge, the patient's temperature did not settle completely but fluctuated between 98° and 100°F for no evident reason.

On Nov. 8 the patient developed a deep femoral thrombosis. Treatment with heparin, kindly suggested by Prof. A. Kekwick, was followed by uninterrupted recovery. All the skin lesions were healed by the middle of November, and the patient was discharged from hospital on Dec. 6. By this time she felt well, though naturally weak.

COMMENT

Spontaneous remission is a familiar occurrence in bullous diseases and it would be most rash to claim that this patient's apparent recovery resulted from the administration of aureomycin. The first few days of this treatment, however, coincided with such a dramatic change as to leave a strong clinical impression that the antibiotic produced the improvement. Immediately before treatment was started the prognosis was indeed grave; after the first dose of aureomycin not one single fresh lesion appeared, and within forty-eight hours the patient's condition had enormously improved. Remission was complete and the patient left hospital apparently cured. It seems, therefore, that a further trial of aureomycin in the treatment of pemphigus is warranted.

CARBON TETRACHLORIDE POISONING

R. W. E. WATTS
M.B. Lond., M.R.C.P.
LATE CAPTAIN, R.A.M.C., GRADED PHYSICIAN

CARBON tetrachloride is a well-known hepatotoxic agent. The following case, in which damage to the heart and kidneys dominated the picture, is recorded to emphasise the less widely appreciated toxic actions of this substance, and the clinical manifestations to which they may give rise.

Apart from injury to the skin and conjunctiva caused by direct contact, poisoning by carbon tetrachloride may occur by inhalation (McGuire 1932, Gautier et al. 1933, Dudley 1935, Graham 1938, Clinton 1947, Squires 1948) and by ingestion (Massachusetts General Hospital 1948, Burns 1946).

CASE-RECORD

A man, aged 59, was admitted to hospital twelve days after drinking about 2 oz. of carbon tetrachloride. Immediately after swallowing the poison he had felt severe generalised abdominal pain, and a few moments later he had become unconscious. On recovering consciousness eighteen hours later he had complained of headache, diarrhœa, and general malaise, but had reported for duty. Thereafter the patient had eaten very little food because "everything tasted of carbon tetrachloride" and he "felt sick"; his bowels had not moved for ten days before his admission. A colleague reported that the patient had performed his usual clerical duties satisfactorily, but had often complained of general malaise, headache, lethargy, and mental confusion. The symptoms had become progressively more severe, and the patient had had to stop work eleven days after the accident. His past medical and family histories contained no relevant details. He had been in the habit of drinking a bottle of spirits a week, and had travelled extensively in both temperate and tropical climates.

SUMMARY

Epidemics of influenza are known to develop in Ocean Island soon after the periodic arrivals of Chinese labourers from Hong-Kong.

An epidemic of influenza A in the island in 1948 was studied clinically and bacteriologically.

The incidence of clinical cases was about 15% among whites, and almost 100% in native Ellice Islanders, but no clinical cases appeared among the 800 Chinese.

Serological evidence suggests that there was a high incidence of subclinical infection in the Chinese.

The island would provide suitable material for testing the effects of immunisation against influenza.

We wish to thank Prof. F. M. Burnet, F.R.S., for his advice and criticism, and the British Phosphate Co. for their collaboration.

PEMPHIGUS VULGARIS TREATED WITH AUREOMYCIN

F. Ray Bettley
M.D. Lond., F.R.C.P.
DERMATOLOGIST TO THE MIDDLESEX HOSPITAL

The curative treatment of pemphigus vulgaris has been so unsatisfactory that it is inevitable that new remedies, particularly antibiotics, will constantly be tried. In the following case 'Aureomycin' appeared to be effective.

CASE-REPORT

A middle-aged woman of German Jewish origin, whom I first saw on Sept. 5, 1949, then complained of sores inside the mouth since about the beginning of July, followed a month later by blisters and sores on the trunk. At that time there were very many superficial erosions on the mucous membrane of the cheeks, gums, and lips. A few scattered blisters up to $1^1/_2$ inches in diameter were to be seen on the back of the trunk, together with a few groups of smaller vesicles. The clinical diagnosis was pemphigus vulgaris; hospital admission was refused, and liquor arsenicalis, 3 minims t.d.s. by mouth, was started.

The patient's condition deteriorated considerably, and on Sept. 20 she was admitted to hospital. The clinical picture of pemphigus vulgaris was then well developed. Blisters, and the sores resulting from them, covered a large part of the trunk, scalp, thighs, and legs. There was also a purulent paronychia of staphylococcal type; for this reason, more than because of the pemphigus, procaine penicillin was given. A week's treatment (450,000 units twice daily) was without apparent effect on the pemphigus, fresh lesions of which were appearing every day. A FIXED SKIN ERUPTION DUE TO PHENYTOIN SODIUM

R. D. Sweet
M.B. Camb., M.R.C.P.
SENIOR REGISTRAR, SKIN DEPARTMENT, ST. THOMAS'S HOSPITAL, LONDON

Since phenytoin sodium or 'Epanutin' (sodium diphenyl hydantoinate) was first introduced by Merritt and Putnam [1] it has been known to cause skin lesions in some patients. Skin eruptions seem more common in children and probably occur in some degree in 5–10% of all people treated with this drug.

Merritt and Putnam [1] stated that the commonest skin changes were scarlatiniform and morbilliform rashes, which usually appeared about a fortnight after the beginning of treatment and were often accompanied by fever and sometimes by eosinophilia. In some mild cases the phenytoin sodium was continued and the rash disappeared; in many it was withheld until the rash faded and then given again without further trouble; but in a few cases the rash recurred each time phenytoin sodium was given. In one case the rash was severe enough to be classed as an exfoliative dermatitis, but this cleared within three weeks of stopping treatment. In another case purpura developed but faded although the phenytoin sodium was continued. Later Merritt and Putnam [2] mentioned a case, not their own, in which there was a "severe generalised dermatitis with bleb formation, and with subsequent desquamation."

Between 1939 and 1942 there were numerous reports of clinical trials with phenytoin sodium and hypertrophic gingivitis became well known as a complication, but no others came to light until 1943, when Barton and O'Leary [3] reported a "fixed" eruption due to phenytoin sodium—a fixed eruption being one in which the same areas of skin always react to a certain drug. Their case is very similar to the present one, and is the only previously published case of this type that I have been able to trace. In both cases the patient was an adult who had been taking phenytoin sodium regularly for some months (and then for two years spasmodically in their case), and in both the eruption was reproduced within an hour or two by a single dose of 0·1 g. Though such cases are very rare, it is important to recognise them. The fact that the patient has been taking phenytoin sodium with impunity for some time may lead him not to mention it when giving his history.

CASE-RECORD

The man was first seen in April, 1946, when he was aged 77 and gave a month's history of recurring blisters on his scalp, forehead, and right shin. He was in excellent health for his age until his skin trouble began, apart from occasional attacks of petit mal, for which he had been taking phenytoin sodium for two months. The differential diagnosis lay between pemphigus vulgaris and a drug eruption, and as a first step the patient was advised to stop any form of internal medication.

Within three weeks his rash cleared completely, and he remained well until March 26, 1949. Three days later he was admitted to hospital with a severe extensive bullous eruption. His forehead and the anterior half of his scalp were covered with large bullæ, many of which had broken leaving raw areas up to 2 in. in diameter. There were also single bullæ on each cheek, the back of his chest, the lumbar region, the dorsum of his left hand, and his right shin. The day after his admission further lesions appeared on his left shin and on his penis.

The bullæ were thin-walled and $^{1}/_{2}$–2 in. in diameter, and mostly broke within twenty-four hours of their appearance. They arose from skin which had first assumed a dusky plum colour, so that the fully developed lesion was surrounded by a dark halo. This had the effect, because of the extensive involvement of his face, of making him look extremely cyanosed as he lay in bed, and it was surprising to find that his unaffected skin was a normal colour.

Apart from his rash the patient was well. He had no fever, and his pulse-rate and respiration-rate were unaffected. His mental condition had, however, deteriorated considerably since he was first seen in 1946. This was ascribed to progressive cerebral arteriosclerosis. His memory had become greatly impaired. He could remember neither how long he had had his blisters nor any of the events leading to their appearance, and he denied ever having the trouble before or previously attending this hospital. His blood-count was within normal limits, except for an eosinophilia of 8%.

Once again the diagnosis lay between pemphigus and a drug eruption. Tulle gras was applied. No drugs were given.

In three weeks all the lesions had healed, and there was no further spread. During his first week in hospital the patient had two "blackouts" lasting a few seconds, in one of which he wetted his bed. These attacks may have been petit mal, but they may equally well have been due to his impoverished cerebral circulation.

As soon as his lesions had healed, the patient was given a test dose of phenobarbitone gr. $^{1}/_{2}$ without ill effect. Next day he was given phenolphthalein gr. $^{1}/_{8}$, as his eruption much resembled that occasionally produced by that drug, but again without effect. Finally, on the next afternoon, he was given phenytoin sodium gr. $1^{1}/_{2}$. The result was dramatic—within three hours all the previously affected areas on his face and scalp became a dusky plum colour, and next day he had a bulla an inch in diameter on his forehead and sharply demarcated plum-coloured macules, also about an inch in diameter, on the back of his left hand and on his right shin. The lesions ceased to progress after twenty-four hours and were beginning to fade four days later, when he was discharged.

COMMENT

The reproduction of the eruption, even to the appearance of the bullæ, seems conclusive proof that this man's pemphigus-like eruption was due to phenytoin sodium. Further, the rash produced by the test dose was confined to sites previously affected, though not all these were involved the second time. The original attack three years ago also had the same limited distribution. It is therefore justifiable to class this case as a fixed eruption caused by phenytoin sodium.

I wish to thank Dr. G. B. Dowling for permission to publish this case.

REDUCTION OF SUPRACONDYLAR FRACTURES OF THE HUMERUS

WITH BACKWARD DISPLACEMENT

J. J. Shipman
M.B. Lond., F.R.C.S.
ASSISTANT LECTURER IN SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

There are two varieties of supracondylar fracture of the humerus. In one the distal fragment is displaced backwards and the cleavage line passes from the anterior surface of the humeral shaft upwards and backwards; in the other the distal fragment is displaced forwards and the line of fracture is downwards and backwards. I am concerned here with the first of these—the backward displacement.

Several methods have been evolved for reducing this variety of supracondylar fracture and the similar displacement which occurs in posterior dislocation of the elbow-joint. These methods have been well tried and are usually successful; but difficulty on several occasions has prompted the development of still another method, which has succeeded where the standard ones have failed. Skeletal traction and open reduction have been avoided because of the stiff elbow which still follows their use.

Ne day he was given phenolphthalein gr. $^1/_8$, as his eruptio much resembled that occasionally produced by that drug, bu again without effect. Finally, on the next afternoon, he wa given phenytoin sodium gr. $1^1/_2$. The result was dramatic—within three hours all the previously affected areas on h face and scalp became a dusky plum colour, and next da he had a bulla an inch in diameter on his forehead an sharply demarcated plum-coloured macules, also about a inch in diameter, on the back of his left hand and on h right shin. The lesions ceased to progress after twenty-fou hours and were beginning to fade four days later, when h was discharged.

COMMENT

The reproduction of the eruption, even to the appea ance of the bullæ, seems conclusive proof that this man' pemphigus-like eruption was due to phenytoin sodium Further, the rash produced by the test dose was confine to sites previously affected, though not all these wer involved the second time. The original attack thre years ago also had the same limited distribution. It i therefore justifiable to class this case as a fixed eruptio caused by phenytoin sodium.

I wish to thank Dr. G. B. Dowling for permission to publish this case.

REDUCTION OF SUPRACONDYLAR FRACTURES OF THE HUMERUS

WITH BACKWARD DISPLACEMENT

J. J. Shipman
M.B. Lond., F.R.C.S.
ASSISTANT LECTURER IN SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

There are two varieties of supracondylar fracture of the humerus. In one the distal fragment is displaced backwards and the cleavage line passes from the anterior surface of the humeral shaft upwards and backwards; in the other the distal fragment is displaced forwards and the line of fracture is downwards and backwards. I am concerned here with the first of these—the backward displacement.

Several methods have been evolved for reducing this variety of supracondylar fracture and the similar displacement which occurs in posterior dislocation of the elbow-joint. These methods have been well tried and are usually successful; but difficulty on several occasions has prompted the development of still another method, which has succeeded where the standard ones have failed. Skeletal traction and open reduction have been avoided because of the stiff elbow which still follows their use.

A FIXED SKIN ERUPTION DUE TO PHENYTOIN SODIUM

R. D. SWEET
M.B. Camb., M.R.C.P.
SENIOR REGISTRAR, SKIN DEPARTMENT, ST. THOMAS'S HOSPITAL, LONDON

SINCE phenytoin sodium or 'Epanutin' (sodium diphenyl hydantoinate) was first introduced by Merritt and Putnam [1] it has been known to cause skin lesions in some patients. Skin eruptions seem more common in children and probably occur in some degree in 5–10% of all people treated with this drug.

Merritt and Putnam [1] stated that the commonest skin changes were scarlatiniform and morbilliform rashes, which usually appeared about a fortnight after the beginning of treatment and were often accompanied by fever and sometimes by eosinophilia. In some mild cases the phenytoin sodium was continued and the rash disappeared; in many it was withheld until the rash faded and then given again without further trouble; but in a few cases the rash recurred each time phenytoin sodium was given. In one case the rash was severe enough to be classed as an exfoliative dermatitis, but this cleared within three weeks of stopping treatment. In another case purpura developed but faded although the phenytoin sodium was continued. Later Merritt and Putnam [2] mentioned a case, not their own, in which there was a "severe generalised dermatitis with bleb formation, and with subsequent desquamation."

Between 1939 and 1942 there were numerous reports of clinical trials with phenytoin sodium and hypertrophic gingivitis became well known as a complication, but no others came to light until 1943, when Barton and O'Leary [3] reported a "fixed" eruption due to phenytoin sodium—a fixed eruption being one in which the same areas of skin always react to a certain drug. Their case is very similar to the present one, and is the only previously published case of this type that I have been able to trace. In both cases the patient was an adult who had been taking phenytoin sodium regularly for some months (and then for two years spasmodically in their case), and in both the eruption was reproduced within an hour or two by a single dose of 0·1 g. Though such cases are very rare, it is important to recognise them. The fact that the patient has been taking phenytoin sodium with impunity for some time may lead him not to mention it when giving his history.

CASE-RECORD

The man was first seen in April, 1946, when he was aged 77 and gave a month's history of recurring blisters on his scalp, forehead, and right shin. He was in excellent health for his age until his skin trouble began, apart from occasional attacks of petit mal, for which he had been taking phenytoin sodium for two months. The differential diagnosis lay between pemphigus vulgaris and a drug eruption, and as a first step the patient was advised to stop any form of internal *medication*.

Within three weeks his rash cleared completely, and he remained well until March 26, 1949. Three days later he was admitted to hospital with a severe extensive bullous eruption. His forehead and the anterior half of his scalp were covered with large bullæ, many of which had broken leaving raw areas up to 2 in. in diameter. There were also single bullæ on each cheek, the back of his chest, the lumbar region, the dorsum of his left hand, and his right shin. The day after his admission further lesions appeared on his left shin and on his penis.

The bullæ were thin-walled and $^1/_2$–2 in. in diameter, and mostly broke within twenty-four hours of their appearance. They arose from skin which had first assumed a dusky plum colour, so that the fully developed lesion was surrounded by a dark halo. This had the effect, because of the extensive involvement of his face, of making him look extremely cyanosed as he lay in bed, and it was surprising to find that his unaffected skin was a normal colour.

Apart from his rash the patient was well. He had no fever, and his pulse-rate and respiration-rate were unaffected. His mental condition had, however, deteriorated considerably since he was first seen in 1946. This was ascribed to progressive cerebral arteriosclerosis. His memory had become greatly impaired. He could remember neither how long he had had his blisters nor any of the events leading to their appearance, and he denied ever having the trouble before or previously attending this hospital. His blood-count was within normal limits, except for an eosinophilia of 8%.

Once again the diagnosis lay between pemphigus and a drug eruption. Tulle gras was applied. No drugs were given.

In three weeks all the lesions had healed, and there was no further spread. During his first week in hospital the patient had two "blackouts" lasting a few seconds, in one of which he wetted his bed. These attacks may have been petit mal, but they may equally well have been due to his impoverished cerebral circulation.

As soon as his lesions had healed, the patient was given a test dose of phenobarbitone gr. $^1/_2$ without ill effect. Next day he was given phenolphthalein gr. $^1/_8$, as his eruption much resembled that occasionally produced by that drug, but again without effect. Finally, on the next afternoon, he was given phenytoin sodium gr. $1^1/_2$. The result was dramatic—within three hours all the previously affected areas on his face and scalp became a dusky plum colour, and next day he had a bulla an inch in diameter on his forehead and sharply demarcated plum-coloured macules, also about an inch in diameter, on the back of his left hand and on his right shin. The lesions ceased to progress after twenty-four hours and were beginning to fade four days later, when he was discharged.

COMMENT

The reproduction of the eruption, even to the appea ance of the bullæ, seems conclusive proof that this man pemphigus-like eruption was due to phenytoin sodiun Further, the rash produced by the test dose was confine to sites previously affected, though not all these we involved the second time. The original attack thre years ago also had the same limited distribution. It i therefore justifiable to class this case as a fixed eruptio caused by phenytoin sodium.

I wish to thank Dr. G. B. Dowling for permission to publis this case.

REDUCTION OF SUPRACONDYLAR FRACTURES OF THE HUMERUS

WITH BACKWARD DISPLACEMENT

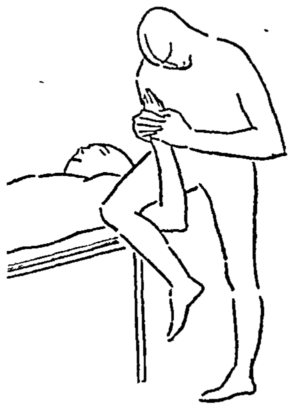
J. J. Shipman
M.B. Lond., F.R.C.S.
ASSISTANT LECTURER IN SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

There are two varieties of supracondylar fracture of the humerus. In one the distal fragment is displaced backwards and the cleavage line passes from the anterior surface of the humeral shaft upwards and backwards; in the other the distal fragment is displaced forwards and the line of fracture is downwards and backwards. I am concerned here with the first of these—the backward displacement.

Several methods have been evolved for reducing this variety of supracondylar fracture and the similar displacement which occurs in posterior dislocation of the elbow-joint. These methods have been well tried and are usually successful; but difficulty on several occasions has prompted the development of still another method, which has succeeded where the standard ones have failed. Skeletal traction and open reduction have been avoided because of the stiff elbow which still follows their use.

TECHNIQUE

The method described requires no assistant or appliances. The patient is placed on a low table and a eneral anæsthetic is administered. Unhurried traction applied to the limb in line with its long axis and is hen continued while the arm is brought into flexion; his avoids damage to the neurovascular structures in front of the elbow-joint which lie dangerously near the sharp anterior edge of the proximal fragment.



The shoulder is abducted to 45°, and the arm is placed in the plane of the body. The manipulator stands above the shoulder and passes his flexed thigh astride the patient's arm just above the fracture line. The thigh now maintains downward fixed pressure against the anterior aspect of the lower end of the upper fragment while the hand is pulled vertically upwards against it by both hands of the manipulator (see figure). The opposed broad and fleshy thigh muscles exert a firm pressure on the fragment without damage to vessels, nerves, or traumatised tissues.

Lateral malalignment can be remedied by applying pressure with the flat of the hand. The arm is put up with the elbow flexed, provided the pulse is present, at an angle of 45°. A deep posterior plaster gutter is applied to prevent subsequent anteroposterior and lateral displacement.

FATAL CHRONIC TRACHEOBRONCHITIS DUE TO PSEUDOMONAS PYOCYANEA IN TWO SIBLINGS

J. R. O'Brien
M.A., B.M. Oxfd
LATE GRADUATE ASSISTANT IN PATHOLOGY, RADCLIFFE INFIRMARY, OXFORD

Pseudomonas pyocyanea and the green pus it produces in the body have long attracted attention. The published work, which goes back to the nineteenth century, has been reviewed by Fraenkel (1917), Lode (1929), Waite (1908), and Epstein and Grossman (1933), who all agree that the infection is most common in infants and children, in whom it is far more serious than in adults. Almost all organs can be infected, the commonest site being the skin, where chronic ulcers are produced, the so-called ecthyma gangrænosum; otitis media, particularly in children, is not infrequently due to this organism. Lung infection usually produces a rapidly fatal hæmorrhagic bronchopneumonia, and bronchitis may occur, but only as an incident in rapid pulmonary spread. Ritchie (1901) found *Ps. pyocyanea* together with hæmolytic streptococci and staphylococci in three cases of bronchitis; his case 47 might have been similar to those I am reporting, but the bacillus observed was not cultured. The alimentary tract (where the organism is a fairly common benign saprophyte), the meninges, the urinary tract, and the bones, may all be the seat of infection, a terminal septicæmia being common.

CASE-RECORDS

Case 1.—A boy, the third child in the family, who had been born normally with a birth weight of 7 lb. 9 oz., passed green stools at the age of 14 days, wherefore the quantity of breast-milk was reduced. At the age of 3 weeks he developed a frequent and exhausting cough of a moist laryngeal type; at the age of 5 weeks he began to vomit and have diarrhœa.

On admission at the age of 10 weeks he weighed 8 oz. less than at birth. He was almost afebrile, with pulse-rate 130 and respirations about 35 per min.

Progress.—Throughout his stay in hospital his condition remained almost unaltered. The cough and occasional attacks of vomiting persisted, and his stools were at times formed and yellow and at others frequent (up to two per feed), loose, green, and offensive. He barely maintained his birth weight, and his weight at death was only 6 lb. 15 oz. During the last week of his life he became increasingly weak and unable to cough, with terminal œdema of hands and feet. The right ear-drum appeared a little red and bulging, and a myringotomy was done. The boy died, after 8 weeks in hospital, at the age of 18 weeks.

Investigations.—When he was 10 weeks old a profuse growth of *Ps. pyocyanea* was grown from the baby's stool. A barium meal and laryngoscopy showed no abnormality. At 12 weeks a postnasal swab grew a pure culture of *Ps. pyocyanea*; the same organisms and *Bact. coli* were isolated from the urine but, since no pus cells were seen, these may well have been fæcal contaminants. Radiography of the chest at this time showed evidence of emphysema and peribronchial inflammation. At 15 weeks a pharyngeal swab grew a practically pure culture of *Ps. pyocyanea*, which was inhibited in vitro by sulphadiazine and very slightly by sulphacetamide, but not by sulphathiazole, sulphadimidine, sulphanilamide, sulphapyridine, or penicillin. The child's hæmoglobin varied between 80% and 100%, and the total white-cell count between 17,000 and 22,000 (11,000 once) per c.mm. The differential counts averaged: band forms 17%, segmented neutrophils 23%, lymphocytes 45%, monocytes 10%, and eosinophils 5%.

Treatment.—On admission the patient was given sulphadiazine 0·5 g. four-hourly by mouth for 5 days. During his third week in hospital, when 13 weeks old, he was given 5000 units of penicillin intramuscularly three-hourly for six days, and later sulphadiazine 0·25 g. four-hourly and intratracheal 'Phenoxetol' (Gough et al. 1944) for eight days, a watery solution of phenoxetol being placed in a Collinson inhaler, which atomises the solution. No treatment seemed to have any effect. A slow transfusion of blood and plasma was given two days before death.

Necropsy Findings.—Only the significant findings are reported here. The larynx and trachea were filled with greenish purulent material; the bronchi and lower end of the trachea were congested; and both lungs showed massive bronchitis and bronchiolitis and pneumonia. Thick greenish pus was squeezed from the cut ends of the bronchi. A swab from the cut surface of the lung showed few pus cells and numerous gram-negative rods, which proved on culture to be *Ps. pyocyanea.*

Case 2.—The fourth child, a daughter, was born 10 months after the death of her brother (case 1). Her birth and neonatal life were not remarkable until she was 6 weeks, when she developed a cough. By the age of 11 weeks she started whooping and continued to whoop for about a fortnight, and occasionally she vomited as well. The cough then became worse, but the baby was gaining weight. She was admitted when 18 weeks old because she had recently developed severe attacks of paroxysmal coughing and choking during which she brought up thick white sputum and became cyanosed and limp.

On admission her temperature was 100°F, pulse-rate 140, respirations 60 a minute. She weighed 12 lb. and was a well-nourished baby with slight subcostal diaphragmatic traction during inspiration. On auscultation of her lungs patches of crepitations were heard, but radiologically the lungs appeared normal.

Progress.—Throughout her stay in hospital her sleep and feeding-times were often interrupted by bouts of distressing coughing, during which she became cyanosed and exhausted and sometimes vomited. She often brought up stringy frothy whitish-green purulent sputum. The patches of crepitations in her lungs came and went, but the radiological appearances remained normal. The fever on admission persisted for a week, with an occasional reading of 103°F, after which it fell by lysis to normal levels and remained so throughout her stay in hospital. Her pulse-rate remained about 140, and the respiration-rate fell during a month to 35 a minute and then slowly rose again to about 50. Her condition remained stationary, her weight on discharge being 11 lb. 14½ oz.; no treatment appeared to have had any beneficial effect. She was discharged, after 10 weeks in hospital, because it was felt that no active treatment could help her, and she died at home at the age of 9½ months, some 5 months after the onset of the infection. No necropsy was done.

Treatment.—On admission the patient was given sulphadiazine 1 g. six-hourly by mouth for 3 days and intramuscular injections of 20,000 units of penicillin three-hourly for a month. After the sulphadiazine had been stopped, 50,000 units (equivalent to 50,000 µg.) of streptomycin was given six-hourly for 4 days. Just over a month later a second course of 50,000 units of streptomycin six-hourly was given for 4 days and 125,000 units for a further 3 days. At the same time, but continuing for a month, intratracheal streptomycin was given with a Collinson inhaler, using a solution containing 50,000 units of streptomycin per ml. The inhalations were given for 10 minutes at a time either after every feed or two-hourly. Scarcity of streptomycin prevented our giving the drug for as long as we would have liked. The patient was also given a course of aerosporin (polymyxin A; Ainsworth et al. 1947), 4·8 mg. being injected subcutaneously three-hourly. After 48 hours of this treatment the patient's urine contained 80 mg. of protein per 100 ml., whereas in previous repeated examinations of "clean" urine I had found 10–20 mg. per 100 ml. It was decided to continue treatment, but next day, after 72 hours' treatment, the urine contained more than 1000 mg. of protein per 100 ml., and over 1000 cells of renal epithelial type and numerous granular casts per c.mm. Treatment was stopped, but the patient passed no urine for 14 hours. When diuresis was re-established, the protein content of the urine fell quickly to 100 mg. per 100 ml., which level was maintained till her discharge 9 days after the end of treatment. On the patient's discharge her urine still contained 20 epithelial cells per c.mm., a few pus cells, and an occasional cellular cast. She was also given a week's course of short-wave diathermy to the upper part of her chest and neck. Apart from the serious toxic effects of the aerosporin, no treatment appeared to influence her clinical condition. The amount of sputum and the frequency of paroxysms of coughing varied slightly but did not seem to be attributable to the treatment she was receiving at the time.

Investigations.—On admission the patient's sputum contained pus cells and very numerous gram-negative rods, which proved on culture to be *Ps. pyocyanea.* This organism was sensitive to aerosporin 2·5 µg. per ml. but not sensitive to streptomycin 5 µg. per ml. On fourteen other occasions *Ps. pyocyanea* was recovered, usually in large numbers, from the sputum or from laryngeal swabs. On two occasions no *Ps. pyocyanea* was grown, but swabs taken next day gave a heavy growth. On the three occasions that her stools were cultured they gave a profuse growth of *Ps. pyocyanea.* Her hæmoglobin level remained within normal limits, and the total white-cell count was 11,000–20,000 per c.mm. Throughout the period of observation she had a lymphocyte-count of between 5000 and 10,000 per c.mm.

INVESTIGATION OF FAMILY

The mother and father and the two elder sisters seemed to be well; *Ps. pyocyanea* was never isolated from nose or throat swabs, nor was it isolated from the stools of the mother, father, and one daughter, but on the one occasion on which they were examined the stools of the other daughter produced a moderate growth of *Ps. pyocyanea.*

SUMMARY AND COMMENT

A baby boy, aged 10 weeks, was admitted to hospital with a very troublesome, exhausting, and productive cough. He was found to have a tracheitis and bronchitis due to *Ps. pyocyanea*; all treatment was unavailing, but he survived for 8 more weeks.

Almost within a year a newborn sister of his developed whooping-cough at the age of 6 weeks. She never completely recovered; the cough persisted, and she was admitted when 18 weeks old with an identical type of productive and exhausting cough and the same tracheal flora. No treatment had any effect, and she died at the age of 9½ months.

Treatment included sulphadiazine, penicillin, streptomycin, phenoxetol, aerosporin, radiant heat, and blood-transfusion. Several of the drugs were given by inhalation as well as systemically. The toxic effect of aerosporin (polymyxin A) on the kidneys—at least in an emaciated baby—were well demonstrated.

The clinical picture of these two siblings was almost identical, and it is remarkable that they both survived so long with such an extensive infection, *Ps. pyocyanea* respiratory infection being usually soon fatal in a baby.

The second baby was infected more than a year after the first had died, and no obvious common source of infection was found. One of the older children in the family produced a moderate growth of *Ps. pyocyanea* on the one occasion when her stools were examined, but such a finding is not uncommon in the normal population. One can only guess whether there exists here a high familial resistance to what is usually a rapidly fatal infection, or whether the two children were infected by a relatively benign strain of *Ps. pyocyanea* which had survived for a year in some common source.

I have to thank Dr. Victoria Smallpeice for permission to report these cases, for most of the clinical data, and for helpful criticism in the preparation of this paper; and Dr. R. L. Vollum for carrying out the sensitivity tests on the organisms isolated. The Wellcome Foundation Ltd. supplied the aerosporin.

URINARY EXCRETION OF PHENOBARBITONE

AFTER A SINGLE LARGE DOSE

A. THOMPSON
B.Sc. Lond., A.R.I.C.
SENIOR SCIENTIFIC OFFICER AND STAFF CHEMIST, HOME OFFICE FORENSIC SCIENCE LABORATORY, PRESTON

A RECENT fatal case of self-inflicted poisoning provided a unique opportunity of following the rate of excretion in the urine of the barbituric-acid derivative, phenobarbitone.

A man, aged 62, who had been given a prescription allowing him gr. 18 of phenobarbitone a week, was alleged to have taken a large dose of the drug during the afternoon of May 2, 1949; this was followed by unconsciousness and coma from which he never recovered. He was admitted to hospital the same day; there he immediately had a stomach washout and was thereafter given stimulants including picrotoxin, strychnine, and nikethamide. He survived five days, but then developed bronchopneumonia and died on May 7. Necropsy confirmed the terminal bronchopneumonia.

Technique.—The urine was examined by precipitating with basic lead acetate, filtering, removing excess lead with sulphuric acid until acid to Congo red, filtering, and extracting with ether (Bamford 1947). The barbiturate was isolated from the other organs by Valov's (1946) sodium tungstate method, in which proteins, &c., are removed by precipitation with sodium tungstate, filtering, and extracting the filtrate with a large volume of ether. Residues were purified with charcoal (Turfitt 1948) and the estimations carried out colorimetrically against known quantities of barbitone using 1% cobaltous acetate and 5% isopropylamine (Koppanyi et al. 1934), both in methyl alcohol.

Findings.—Urine, obtained each day, was found to contain a barbiturate in the following quantities (calculated as barbitone):

Date	*Vol. of urine (ml.)*	*Barbiturate (mg. per 100 ml.)*
May 2	115	1·8
" 3	125	2·4
" 4	176	3·2
" 5	176	4·0
" 6	180	6·0
" 6 (3 P.M.)	360	3·6
" 7	180	2·4

The quantities of barbiturate found in other organs submitted for analysis were:

Organ	*Weight (g.)*	*Barbiturate (mg. per 100 g.)*
Liver	1232	2·7
Kidneys	268	2 0
Spleen	98	2·6
Stomach contents ..	109	trace

These last results agree with the findings of Andrew and Neubauer (1947) that barbiturates are evenly distributed throughout the body.

I wish to thank Dr. A. A. Miller, group pathologist, Preston Royal Infirmary, for the clinical history.

URINARY INCONTINENCE CURED BY OPERATION

AN UNCOMMON CASE

MEAVE KENNY
F.R.C.O.G.
READER IN OBSTETRICS AND GYNÆCOLOGY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

A DIVORCED parous woman, now aged 49, was seen by the late Sir Comyns Berkeley in November, 1937. He found that her cervix uteri was replaced by an ulcer spreading on to the vagina in all directions, the uterus being fixed, with infiltration to the pelvic wall on both sides. This stage-III cancer was treated by the Stockholm method in Lambeth Hospital, radium and X rays being used. I am indebted to Dr. T. Robb, director of radiotherapy there, for his note on the original condition and the progress after treatment. For a year the patient was symptom-free; then rectal tenesmus developed, and during 1939 a horseshoe-shaped fibrous stricture gradually encircled the rectum. By 1942 there were signs of chronic obstruction and fæces were passed per vaginam. A colostomy was done in December of that year. The woman remained very well until early in 1947, when she became incontinent of urine. A vesicovaginal fistula was discovered and slowly increased in size.

In July, 1949, the woman was referred to me by Mr. J. H. Carver, F.R.C.S.

She was in good health, and surface biopsy and vaginal cytology showed apparent complete cure of the cancer. However, save for a thready band about the external orifice, the whole urethra had disappeared; the entire anterior vaginal wall was absent; the ureters opened into a little shrunken pouch near the remains of the cervix; and the rectovaginal septum did not exist. The anal sphincter alone remained intact. Urine constantly flowed over the sore and ulcerated skin of the vulva.

Transplantation of the ureters into the colon seemed to be the obvious treatment, but the seven-year-old colostomy was on the side of the abdomen, near the iliac crest. The comfort of the patient with a "wet" colostomy depends on her being able to wear a bag which can be closely applied to the abdominal wall. This is possible only when the colostomy is central, and best when the abdominal wall has been flattened by removal of the umbilicus.

The only useful structure preserved was the good anus. Therefore, fashioning flaps by splitting the skin of the nymphæ, I closed the whole urogenital orifice and left a large de Pezzer catheter in the anus, where it was tightly held by the sphincter. Constant drainage was maintained for eleven days with twice-daily lavage of the cavity. Healing was perfect. Eventually the patient voided urine through the anus with complete control of the act, and catheterisation thereafter produced a negligible quantity of residual urine. The atresia of the remains of the rectum is apparently so complete as to prevent organisms from the bowel infecting the urine, which has so far remained clear. Thus the prognosis, so far as renal function is concerned, is probably much better than if colonic implantation of the ureters had been done.

Since skin rather than vaginal epithelium has been used to effect the closure, the progressing atrophy of the tissues exposed to radium should not mar the result. The patient is very content.

VOLVULUS OF THE SMALL INTESTINE

THE POSITION OF RELIEF

R. E. B. TAGART
B.M. Oxfd, F.R.C.S.
RESIDENT SURGICAL OFFICER, ROYAL EAST SUSSEX HOSPITAL, HASTINGS

THE following case of small-intestine volvulus is reported because it was of the idiopathic type, which is rare in this country, and because it clearly demonstrated the clinical sign of "position of relief." Early diagnosis is essential for successful treatment, and this sign, when present, is of great value.

CASE-RECORD

A retired plumber, aged 67, was admitted to the Royal East Sussex Hospital at 8 A.M. on Aug. 15, 1948. At 7 A.M. he had taken a glass of effervescent salt mixture. Shortly afterwards he had felt a sudden pain in the right iliac fossa, accompanied by the eructation of gas. As soon as the pain started he had passed a small stool, after which he had passed neither fæces nor flatus. He had vomited small quantities once or twice. The pain, which was agonising, was steady, not colicky, and did not go through to the back. The most comfortable position for the patient was face downwards with the trunk supported, clear of the bed, on his knees and elbows.

During the previous year he had had one or two attacks of similar pain, but these had lasted only two or three minutes.

Examination.—The patient was thin though not emaciated, and was in great pain. When first seen he was in the knee-elbow position; and he returned to this position as soon as his examination was over.

His temperature was 96·4°F; pulse-rate 52 and respirations 20 per min. The abdomen was slightly distended, and there was severe tenderness and some rigidity in the right iliac fossa. These signs were also present—though less prominently—in the right upper quadrant. Peristaltic sounds were normal in quantity but rather hollow, suggesting distension of the gut. An easily reducible right femoral hernia was present. On rectal examination nothing abnormal was detected. The tongue was moist and not furred; there was no fœtor oris. Nothing abnormal was found in the respiratory and cardiovascular systems. The provisional diagnosis was volvulus of the cæcum.

Operation.—At 11.30 A.M., under general anæsthesia, a right paramedian incision was made at the level of the umbilicus. The peritoneal cavity contained straw-coloured fluid. The cæcum was normal in size and position. Almost all the small intestine was dark-blue and slightly distended. It was rotated anti-clockwise on its mesentery through 360°. This volvulus was reduced and the colour of the intestine was immediately restored to normal. The mesentery did not appear to be unduly long or in any way abnormal. The gut was replaced in the abdomen. A band of omentum adherent in the right femoral hernial sac was divided; this band did not appear to be responsible for the volvulus. The abdomen was closed without drainage.

Recovery from the operation was uneventful, apart from some diarrhœa on the 4th day. The patient was discharged to his home, in good health, 12 days after the operation.

Re-admission.—On Dec. 6, 1948, the patient was re-admitted to hospital, complaining once more of abdominal pain. This had come on gradually; it was severe and colicky and was situated around and below the umbilicus. The patient passed flatus while the pain was present. There had been one or two similar attacks since his discharge from hospital. He was found to have slight lower abdominal distension, and some muscle guarding and tenderness were noted at a point 1 in.

below and to the right of the umbilicus; peristaltic sounds were normal. A small, tender, irreducible right femoral hernia was present. There was no position of relief. The patient was observed for some days. His bowels were open regularly; he did not vomit; his pain gradually disappeared.

Second Operation.—On Dec. 22 Mr. D. N. Wilson undertook a Lothiesen repair of the right femoral hernia. The sac was much fibrosed; it was empty. There was a small amount of clear, pale-yellow fluid in the peritoneal cavity. Recovery was uneventful.

When seen at follow-up four months later, the patient reported that he was very well except that after meals he often had a feeling of fullness associated with a dull ache centred around and just above the umbilicus. Physical examination revealed no abnormality. A barium meal, followed through, showed no abnormality.

DISCUSSION

Incidence

McKechnie and Priestley (1936) found that at the Mayo Clinic between 1910 and 1935 there were 37 operations for small-intestine volvulus. In only 3 of these could no cause be demonstrated. Of the 34 patients operated on in this series 22 were males and 12 females.

The disease is rare in Europe and America but much more common in other parts of the world. Kerr and Kirkaldy-Willis (1946), in Kenya, treated, in one year, 21 cases of acute intestinal obstruction in Africans, and in a third of these the obstruction was due to volvulus of the small intestine. McWatters (1945) reports that the disorder is fairly common in India.

Pathology

Abnormal length of narrowness of the mesentery, Meckel's diverticulum with or without an umbilical band, malrotation of the large intestine leaving an abnormally long small-intestine mesentery, and exomphalos are the congenital lesions which have been found in association with small-intestine volvulus. One of these lesions was present in 8 of the 37 in the Mayo Clinic series. Dott (1923) has described the gross developmental errors which are the cause of intestinal volvulus neonatorum.

Where incomplete midgut rotation is the basic lesion one can expect to find that the mesenteric attachment of the small intestine or cæcum is abnormal. The normal rotation of the midgut is in an anti-clockwise direction; clockwise rotation sometimes causes intestinal obstruction. In the present case all mesenteric attachments appeared normal and the rotation of the mesentery was anti-clockwise; thus it seems unlikely that a congenital error in midgut rotation was concerned in causing the volvulus.

Cases arising from acquired causes numbered 26 of the 37 in the series of McKechnie and Priestley; there were 14 with postoperative adhesions, 2 with inflammatory adhesions, 5 with adhesions of unknown cause, and 2 with internal herniæ, while in 3 cases the patients were still in hospital after a recent operation. Allen and Welch (1947) say that foreign bodies, such as food boli and masses of worms, or tumours of the small intestine, can cause volvulus.

Kerr and Kirkaldy-Willis (1946) and McWatters (1945) agree that the frequency of small intestine volvulus among their patients is attributable to the bulky, farinaceous nature of their diet, which causes intestinal distension. In the case reported here pain started very shortly after swallowing an effervescent salt mixture, which would be quite capable of causing sudden and extensive dilatation of the small intestine. The patient's history suggested that during the previous year there had been one or two episodes of incomplete or temporary volvulus. Probably his small intestine lay permanently in a position of partial rotation, not enough to cause pain or interfere with the blood-supply. The sudden distension by the gas of the effervescing mixture caused the rotation to increase to one complete turn. Sweet (1935) believes that meteorism of dietary origin is a contributory cause of volvulus of the cæcum.

The volvulus may reduce itself spontaneously; but if this does not happen the mesenteric blood vessels become blocked, necrosis of the gut rapidly follows, and the patient dies from peritonitis.

Symptoms

In the present case and in Woods's (1945) case, there had been minor attacks of abdominal pain during the year before the final catastrophe. McKechnie and Priestley (1936) report a case in which attacks of pain had recurred for the thirty years before the main attack. Gardiner (1947) mentions that acute volvulus of the cæcum is sometimes preceded by a number of minor attacks.

The onset of the pain depends on the pathological lesion, but is usually sudden. In idiopathic cases, where no band or other cause is present, very sudden onset —as in the case reported here—would be expected.

An important factor in the origin of the pain is tension on the mesentery. Pain from such tension very commonly goes through to the back, and is steady, not colicky. Whether the pain with volvulus is predominantly steady or colicky depends upon the relative contributions to its severity from abnormal obstructive peristalsis and from mesenteric tension.

In the early stages, frequent small reflex vomits are usual; obstructive vomiting follows later.

The Position of Relief

An outstanding clinical feature is the effect of assuming the position of relief, to which the patient returns whenever he is left alone. This position is often, as in the case reported here, the knee-elbow position; but Evans and Bigger (1947), who first described the sign, which, they said, is very common with small-intestine volvulus, reported that the patient may be found lying on his right or left side. For each patient the position is constant and any change from it increases his discomfort.

This sign is important in diagnosis; but it is not always present, for where the volvulus is caused by a tight band which holds the gut firmly in position, no alteration in the position of the patient will cause any change in mesenteric tension with accompanying relief of pain. Where, however, there is no tight band or constriction and rotation alone is the cause of the condition, change in position is likely to relieve the tension on the mesentery with consequent lessening of the pain.

EXAMINATION

In the present case the patient's clean moist tongue and slow pulse gave no indication of the gravity of his condition.

In the early stages abdominal examination reveals nothing very characteristic. The signs are those of early small-intestine obstruction with some tenderness and rigidity; in the present case, this was most pronounced in the right lower quadrant. When this patient was examined within two hours of the onset of complete volvulus, peristaltic sounds were still audible, but were hollow. The abdomen was silent in 5 of the 7 cases reported by Kerr and Kirkaldy-Willis, even though most of them reached hospital within a few hours of onset.

Treatment

Immediate operation is essential. With idiopathic volvulus, the treatment consists of untwisting the mesentery, with or without resection of gut. Where a cause is found, this should, if possible be corrected. If the condition is far advanced intestinal suction, parenteral replacement of body fluids, electrolytes, and colloids, and chemotherapy may be necessary.

Prognosis

The immediate prognosis depends very largely on the speed with which the diagnosis is made and treatment started. If, as in the case here reported, the condition is relieved within a few hours, the immediate outlook s excellent. When operation is not performed until necrosis of the gut and peritonitis have set in, the risk of death is high.

Of the 31 cases surviving the original operation in the series of McKechnie and Priestley, 19 (60%) were subsequently quite free of symptoms. In 12 (38%) abdominal pain recurred; and in 5 of these a further operation was necessary. In 2 patients (6%) the volvulus was found to have recurred: and in 1 of these it recurred twice.

A complete volvulus is very commonly preceded, over a period of years, by attacks of subacute or incomplete volvulus. The evidence suggests that this partial volvulus can be transformed into complete torsion by sudden distension of the small intestine. Patients in whom this disorder has been recognised should therefore be warned that it is dangerous for them to drink rapidly a large quantity of fluid, and that effervescent drinks may constitute for them a particular peril.

SUMMARY

A case of idiopathic volvulus of the small intestine is reported. The causes of small intestine volvulus are enumerated, and the importance of early operation emphasised.

The sign of "position of relief" is described. When present this is of great diagnostic value.

I wish to thank Mr. D. N. Wilson, under whose care the patient was admitted, for permission to treat the case and to publish this report.

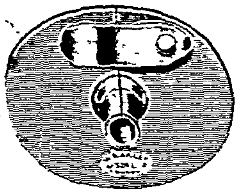
New Inventions

A NEW SUPRAPUBIC SHIELD

THE operation of suprapubic cystostomy may be less used now as a preliminary to prostatectomy, but there remains the group of patients who fare better with the two-stage operation, and there are also many patients who require permanent suprapubic cystostomy for such conditions as inoperable carcinoma of the prostate, injuries of the spinal cord, tabes dorsalis, and disseminated sclerosis. Successful management of the aftercare of these unfortunates is not made any easier by the suprapubic shield in current use—as anyone who has had to persuade a catheter (de Pezzer or Malécot) to slide through the spout of the shield will know.



The modified shield.

The accompanying figure shows a simple modification which permits the catheter and shield to be changed with ease. The upper half of the shield is slit down as far as the spout, which is also slit along its upper surface. This enables the spout to be fitted round the catheter after it has been introduced into the bladder, and then by means of an overlap and stud the spout is made to grip the catheter securely. In this way the patient is saved from feeling any pain and the nurse (or doctor) can change the catheter with a minimum of trouble.

This suprapubic shield is made of steam-cured rubber, and is boilable. The makers are W. H. Bailey & Son Ltd., of 45, Oxford Street, London, W.1.

I wish to thank Sister H. C. Fabian for her help in devising this modification of the shield, and Mr. D. J. Pugh, L.I.B.S.T., of Messrs. W. H. Bailey & Son, for his help in its production.

London, N.W.1. PHILIP HOPKINS, M.R.C.S.

Reviews of Books

Pharmacology and Toxicology of Uranium Compounds

Editors: CARL VOEGTLIN, PH.D., formerly chief of division of pharmacology, National Institute of Health, U.S. Public Health Service: HAROLD D. HODGE, PH.D., professor of pharmacology and toxicology, University of Rochester. New York and London: McGraw-Hill 1949. 2 vols. Pp. 1084. 60s.

THESE two large volumes record an immense amount of investigation, urgently performed, between 1943 and 1946, to determine the risk to, and establish safeguards for, the health of workers concerned with the industrial and scientific use of uranium compounds in relation to the production of atomic energy. The pharmacology division of the University of Rochester undertook the project, with numerous collaborating groups of technical experts—analytical chemists, pathologists, geneticists, engineers—and manifold administrative sections. The result is an admirably complete and detailed account, replete with bibliographies, tables, diagrams, and colour photographs (e.g., of renal histopathology). It should serve as a pattern and as a source-book of techniques for future studies of industrial toxicology. Several prefaces explain the relation of the work to the other U.S. projects on nuclear energy. The 46-page introduction gives the plan of the work and summarises the chief results of each section.

The early chapters deal with the chemistry of uranium compounds, analytical methods, and statistical methods. The main part of the record is concerned with the toxic effects on animals of uranium compounds, administered by various routes. Parenteral and oral administration, and application to skin and to eye, have a chapter each, and much space is given to toxic symptoms after inhalation. The pathology section, chiefly on renal damage, is important. Detailed information is presented on the effects of uranium poisoning, the general pharmacology of uranium, and the development of tolerance. The actions of uranium compounds on enzymes and proteins are recorded, and the measurements of catalase activity of urine is shown to be a sensitive test for their early toxic effect on the kidney. The mechanism of the toxic actions is discussed; evidently particle size, an important factor in the inhalation of a toxic dust, requires further study.

No experiments were permitted on human subjects, but reports are given of the effects of accidental acute exposure, fatal and non-fatal. Protective arrangements were instituted from the beginning of the project, and the findings so far recorded for studies of chronic exposure of workers to uranium are fortunately negative. The pharmacology and toxicity of fluorine and hydrogen fluoride are surveyed in the last chapter.

Paul Ehrlich

MARTHA MARQUARDT. Foreword by SIR HENRY DALE, O.M., F.R.C.P., F.R.S. London: Heinemann Medical Books. 1949. Pp. 255. 25s.

Miss Marquardt, for many years Paul Ehrlich's secretary, has written a notable book about her revered master. In a foreword Sir Henry Dale makes clear to us the achievements of this man of prophetic vision from whose work, as he himself foresaw, modern chemotherapy has developed. Of Ehrlich—lovable, absent-minded, burning with enthusiasm, gesticulating, and loquacious, with a hundred endearing little tricks of speech and manner—Miss Marquardt draws for us a revealing portrait. It is a picture by one who viewed the excitable little man with an adoring love, but who is not blind to his faults. A Jew, Ehrlich was yet a German. Therefore as *Geheimrat*—autocrat of the great institute over which, after long neglect, he was set to preside—he ruled not only by love but by fear. The charming friendliness of the man was sometimes interrupted by bursts of hot anger at what he considered slackness or disobedience, before which all his staff grew pale with fear, and which sometimes ended in the breaking of the culprit's career that others might take warning. When the credit and the immense financial rewards of his great work in the concentration of antitoxins went not to him but to his aristocratic co-worker, Emil von

Behring, his outcry was equal to his indignation. But if the author tells us of these things she does so only to make more clear the blend of virtues which together make up a most unusual and intriguing personality. Nor is she alone in her admiration. Sir Henry Dale, the late Prof. William Bulloch, and Prof. Carl Browning in turn spent some years working with him and all here testify to the enduring affection with which they came to regard him. Miss Marquardt's English book, fascinating in its unexpected details, is worthy of her great German master.

Isotopic Tracers and Nuclear Radiations

with applications to biology and medicine. WILLIAM E. SIRI, University of California. New York and London: McGraw-Hill. 1949. Pp. 653. £5 6*s.* 6*d.*

THIS volume comes from the departments of medical physics and physics and the radiation laboratory at the University of California. Only one section—about a tenth of the whole—is concerned with actual biological and medical applications of tracers. The rest of the book contains a section on essential theoretical conceptions and numerical and mathematical data about isotopes and nuclear radiations; a fairly detailed outline, again with much mathematical data, of the methods and instruments employed in tracer research; and 91 pages of references. The first section seems specially designed to frighten off any non-physicist who thinks of working with tracers. It abounds in statements like:

> The complete expression for the total binding energy may now be written
>
> $$E = aA + bA^{2/3} + cZ(Z-1)A^{1/3} + dI^2A^{-1} + \Delta E$$
>
> where
>
> $$\Delta E = \begin{cases} 0, \text{ for } A \text{ odd} \\ \pm cA^{3/4}, \text{ for } A \text{ even } \begin{bmatrix} Z \text{ even} \\ Z \text{ odd} \end{bmatrix} \end{cases}$$

Such is the formidable jargon of the nuclear physicist. This section contains numerous tables and graphs of essential data; one table—the well-known Seaborg and Perlman table of isotopes—takes up 72 pages. The section on methods is also difficult for the uninitiated, but there are interesting sections on the standardisation of radioactive samples and on the safe handling of radioactive materials. The actual biological and medical section is a disappointing catalogue: this subject has been much better handled by Hevesy, in his book on radioactive indicators.

In a foreword Dr. J. H. Lawrence says of this volume: "For those persons yet unfamiliar with the physical and biological literature in this field, it would appear to provide much of the fundamental material with which he must familiarise himself before attempting intelligent and useful investigations with isotopic tracers and nuclear radiations." He may well be right, and then one glance at this book will convince most medical men that the subject is best left to the specialist; who will probably be glad to get the information in one volume.

Mysterious Marriage

E. GRAHAM HOWE. London: Faber & Faber. 1949. Pp. 320. 15*s.*

IN stating his philosophy of life Dr. Graham Howe is both enlightening and irritating—the first because he has many acute things to say, the second because of the form in which he clothes his argument. The place of the individual in the dynamics of society, and of the "I" in the dynamics of the self, must be the starting-point of any modern philosophy of human conduct. In his study of the spoilt child, who has failed to make the initial adjustment between wish and reality, and between self and other, Dr. Howe is on ground which must be incorporated into our ideas of man. The irritating element in his presentation is that the argument repeatedly takes a mystical or a whimsical turn, in which the clinical observation is submerged; and the effect he leaves is of a man in search of a system on the medieval model. Little cabalistic diagrams, reminiscent of those used by Ouspensky, increase rather than resolve the confusion. Such phenomena as the compulsion neurosis or the asocial behaviour of individuals in modern cultures are suitable subjects for exact investigation, but exactness is the one thing which Dr. Howe nowhere approaches. The result is a blend of interesting speculation, establishe fact, and annoying woolliness. The fairies at the bott of the garden whom Jung invited into the presentatio of social and individual psychology have long outstaye their welcome.

Chemical Activities of Fungi

JACKSON W. FOSTER, professor of bacteriology, Universit of Texas. New York: Academic Press. 1949. Pp. 6 $9.50.

CHEMICAL mycology has now become so vast tha no wonder Professor Foster deliberately chose to lim his monograph to the lower fungi commonly known a moulds. His decision, though wise, may neverthele be regretted by the reader deprived of the chance t become acquainted with mycological problems in th widest sense. However, here we have a book, th first of its kind, which will soon establish itself as standard work on the biochemical activities of th moulds. It is an authoritative, highly critical, an exhaustive treatise dealing with manifold aspects o metabolic processes in moulds. The topics include, fo example, methodology, the chemical nature of th mycelium, biochemical syntheses by mutants, th application of moulds to micro-analysis of metals an vitamins, trace-element nutrition of fungi, formatio of organic acids, extraction and purification of penicilli and enzyme preparations. Professor Foster writ well, and will be admired for the skill and precision wit which he has tackled his difficult and fascinating subjec

Œdipus: Myth and Complex

PATRICK MULLAHY. With an introduction by Eric FROMM. London: Allen & Unwin. 1949. Pp. 53 37*s.* 6*d.*

THIS book starts with the idea that a thorough know ledge of the whole Œdipus myth and its setting are nece sary to evaluate the Œdipus complex; but it makes contribution to such knowledge. To find the Sophocl trilogy reprinted as the second part of the book may a convenience to readers who have no other access it, but at least some comment on it would be welcom from the author. The first part of the book is an accoun as seen through his eyes, of the work of the seve most distinguished psycho-analysts. One is astonishe to learn that these are Freud, Jung, Adler, Otto Ran Karen Horney, Erich Fromm, and Harry Stac Sullivan. One misses Stekel in this galère. In conclusion, the work of these authors—with th exception of the last two—is depreciated in magisterial tone which the interpolation of a fe compliments does little to mitigate.

Surveys of Anatomical Fields

JOSEPH L. SHELLSHEAR, D.S.O., M.D., M.S., researc professor of anatomy, University of Sydney; N. W. G MACINTOSH, M.B., senior lecturer in anatomy at th university. Sydney: Grahame Book Company. 1949 Pp. 172.

DURING the last war Professor Shellshear and Dr Macintosh conducted a correspondence course on anatomy for medical officers on active service by providing dossiers, consisting of essays illustrated by drawings and X-ray [illegible] elve of these essays have now been [illegible] and rewritten in book form. The [illegible] discusses the teaching of anatomy, and emphasises the importance of orthogonal drawings made in the correct anatomical position. The other essays deal with the anatomy of certain selected regions, such as the forearm, pharynx, and pelvis. In most of them some particular landmark is chosen as a foundation for describing the morphology of a given anatomical region. Thus the iliopsoas muscle and the inguinal ligament are discussed as an introduction to the structure of the inguinal region, and the transverse process of the fifth lumbar vertebra as a point from which to correlate the anatomy of the lumbosacral region. The essays were originally designed to stimulate the postgraduate student in anatomy to write similar essays displaying exact expression in writing; by their adherence to topographical minutiæ and emphasis on the synthetic method of approach to anatomy, the authors probably go far towards accomplishing this object.

THE LANCET

LONDON: SATURDAY, JAN. 14, 1950

Civil Service Anomalies

OUR Civil Service is powerful and of high repute: and in return for responsibility, prestige, and security its senior officials have been willing to forgo some of the money their abilities would generally command elsewhere. Even before the war, however, substantial increases in the salaries for the higher posts were overdue: and the expansion of other national services, offering higher rates of pay, has made it less and less defensible that the key men at the centre should be given so little. It is not surprising, therefore, that the First Division Association[1] should have approached the Prime Minister with a request for immediate action on the Chorley Committee's recommendations.[2] In September, 1948, this independent committee proposed that a further £200,000–£400,000 per annum should be allotted to the senior Civil Servants, and the Government agreed to this addition, proceeding by instalments to begin last October. But at the last moment the Chancellor of the Exchequer deferred the new rates until 1951 because devaluation made it urgently necessary not to raise incomes. Since Civil Servants have good reason to understand the dangers of inflation and the value of their example, they might have accepted this decision stoically if it had been generally applied. But they have been galled by the subsequent increase of university salaries, provided out of public funds, and by the offer of salaries at the proposed new rates to technicians urgently required in atomic-energy projects. As the *Manchester Guardian* says:

> "They are the unfortunate victims of circumstance. While the mass of wage-earners have had steady increases of wages over the last ten years the higher-paid civil servants (like the judges and, in less degree, the teachers) have had either no increases at all or relatively small ones. The full brunt of the pressure on the middle classes has fallen on them without any possibility of improving their situation."[3]

A striking example of the present anomalies is the difference between the pay of doctors in different branches of the public service. Salaries in the National Health Service, but not elsewhere, are based on the three Spens reports, which the Government have accepted. Efforts to bring medical salary scales outside the N.H.S. into harmony with the findings of the Spens committees are being made on behalf of doctors in the public-health service,[4] the Armed Forces[5] and the Colonial Service.[6] But the need is perhaps greatest—and the promise so far smallest—for those in the various civilian Government departments at home. Here are to be found discrepancies that would still need removal even without prompting by the Spens standards. For example, in the Ministry of Pensions service a large proportion of the doctors—eight out of ten in one hospital, we are informed—are not on the establishment, though some of these have served for years: and, while receiving the same salary and doing the same work as their established colleagues in comparable appointments, they get no compensation for the withholding of superannuation rights. Then again, this Ministry has been urged, without effect, to grade its more junior posts as in the N.H.S., so that when they later seek other employment these doctors may make their previous experience clear. As to salaries, the Ministry of Pensions pays senior specialists a maximum of only £1400: and similar anachronisms are to be found elsewhere. For example, on the prison service Mr. STANLEY MAYNE, general secretary of the Institution of Professional Civil Servants, has written:

> ". . . a psychiatrist in the prison service has a salary scale of £1000–£1400 a year. A similarly qualified officer in the National Health Service is on a scale of £1700 (linked to age 32) rising by increments of £125 and then of £150 to a maximum, reached in eight years, of £2750. Does this mean that salaries are fixed on a catch as catch can basis? Or that the Government have decided they do not want psychiatrists in the prison service but lack courage to announce the fact? Or, as similar parallels exist between every part of the medical Civil Service and the National Health Service, that it is Government policy to reduce the medical Civil Service to a cipher?"[7]

In conjunction with the British Medical Association and the Ministry of Health Medical Staff Association, the institution has drawn up a proposed scale to align the salaries of medical Civil Servants with those in the National Health Service. At the Ministry of Health the chief medical officer's salary would be increased from £3000 to £5000, and in certain other grades the maximum would be increased by close on £2000. A deputation asked the Treasury last September to express its views on this scale: but we hear that no reply has been received.

About the need for increasing salaries at the highest levels there can be no argument: it is intolerable that the chief medical officer of the Ministry, who is the most important personal link between the professional and the administrative sides of the health service, should have barely more remuneration than the consultant who has not yet gained a merit award. Below him, the existing salaries are such that it is hardly surprising that the Ministry has latterly lost a number of its carefully chosen medical staff—and this at a time when it has greater responsibilities, and greater need of ability, than ever before. There may be varying degrees of enthusiasm for the Civil Service: but if we have one at all—as of course we must—it should offer conditions that will continue to attract, and keep, first-rate men in the principal positions. For clinical work its payment should be substantially the same as is offered by the N.H.S. Mr. MAYNE, unfortunately, was hardly exaggerating the present disadvantages when he wrote:

> "Obviously no parent, knowing the facts, can conscientiously advise or encourage children to devote themselves to a scientific career or to any of the professions in the Civil Service. . . . If this is not what they intend then the Government should give Civil Service salaries that clear and coherent thought they so obviously urgently need."[7]

Streptomycin in Joint Tuberculosis

As in nature, so in the arts and sciences, there are times of recession and times of growth. The treatment of surgical tuberculosis is now emerging from a time of recession. Which of the new methods now being tried will establish itself? In a disease in which recovery is so difficult to assess it may take years to answer this question.

In Johannesburg, STREETEN[1] has been treating tuberculous arthritis with intra-articular streptomycin. The injections of streptomycin, in doses of either 0·25 or 0·5 g., were given daily for ten days and were preceded by the injection of alkali (10–20 ml. of *N*/20 sodium hydroxide and 10–20 ml. of *M*/20 borax as buffer) into the joint to raise the pH of the synovial fluid to 9·0, which according to WAKSMAN and SCHATZ[2] is the optimum pH for streptomycin action. STREETEN reports on only five patients, only one of whom had tubercle bacilli cultured and confirmed on guineapig inoculation, and three others had positive Wassermann reactions. One patient was discharged from hospital as soon as the ten days' course of injections was over, while another had only outpatient treatment. The follow-up periods were very short, and even then a relapse was reported in one patient; but STREETEN was impressed by the relief of symptoms and amelioration in the patient's clinical condition. He refers to the statement of JONES[3] that the intra-articular route is the only satisfactory way of giving penicillin in joint wounds and infections, and certainly the direct application of streptomycin to the diseased area as well as intramuscularly has proved valuable in meningitis. The use of alkali and a buffer is based on STREETEN's observation that arthritic exudates are acidic: it also seems possible that the alkali itself, even without streptomycin, might depress the activity of tubercle bacilli in the joint lesion. Other results of the treatment of joint tuberculosis with streptomycin have been published, though most of this work is still in the speculative stage.

The treatment of sinuses from tuberculous lesions with streptomycin looks promising—DAVIS,[4] for example, finds that the response of sinuses originating in bone is dramatic. He, like BICKEL and his colleagues[5] at the Mayo Clinic, used only the intramuscular route. GALLAND,[6] of the Hôpital Franco-Americain, Berck-Plage, who has treated 40 cases of skeletal tuberculosis with streptomycin, also finds that its beneficial effect on sinuses is remarkable. The prevention of sinus formation or the healing of a persistent sinus from a tuberculous joint is itself a notable advance, and, with penicillin to counteract sepsis, patients with chronic suppuration and advancing amyloid disease should no longer be seen in surgical tuberculosis wards, provided that the first principles of surgery are not forgotten—that effective drainage is provided, sequestra are removed, and sterile dressings are applied.

The future will show what streptomycin can do in early joint lesions, where the cartilage is still intact and there is no caries of bone. MEDLAR[7] has said of pulmonary tuberculosis that once necrosis has occurred the way for the streptomycin to reach the bacillus is barred. What HADFIELD[8] has called the lymphoreticular apparatus must come into action in the defence of the joint against tuberculosis. ALLISON and GHORMLEY[9] have described the close interrelations between the tissue reactions against tuberculosis in the synovial membrane of joints and in the metaphyseal ends of the long bones. The macrophages in these situations are responsible for the destruction of tubercle bacilli. Absorbed by the synovial membrane, the streptomycin would reach the tubercle bacilli both in the membrane and in the metaphyseal bone and exert its bacteriostatic action. But the patient would not be cured of tuberculosis, the healing of which would still depend on the natural processes of repair. So patients will still need constitutional treatment to augment their resistance, though in the patients treated sufficiently early resolution may be more rapid and certain. Once the disease has reached the osseocaseous stage the natural barriers set up to limit its spread will also prevent streptomycin gaining access to bacilli enclosed in the lesion. In such cases streptomycin treatment might well be futile without supplementary surgery. By osteotomy and other surgical means the barriers set up by nature can be broken down, the necrotic areas revascularised, and the reparative processes of bone set in operation, under a protecting "umbrella" of streptomycin which will prevent miliary dissemination and sinus formation and can now also reach the lurking bacilli. If they are to be safe these surgical measures should be carried out only by surgeons with special experience of skeletal tuberculosis, and only after a preliminary period of constitutional treatment to raise the patients' resistance.

When new advances are made it is sometimes at the expense of the old and tried methods. We cannot afford to let this happen in skeletal tuberculosis. If treatment is to be fully effective it must still be based on the teaching of such men as CALVÉ, GAUVAIN, ROLLIER, CALOT, ROBERT JONES, GIRDLESTONE, and PUGH. In short, we must still treat the tuberculous patient and not only the tuberculous joint.

Penicillin and Modern Research

TEN years ago few people had heard of penicillin or of antibiotics, and fewer still were interested in them. Today penicillin is a familiar word throughout the civilised world, and the production of antibiotics has become a great industry, with huge factories and thousands of employees. The small group who were primarily responsible for this amazing transformation have gathered together what is known about these new remedies, and the volumes[10] prepared by FLOREY, CHAIN, and their colleagues, the first two of which have now been published, will be gratefully studied by scientific workers of many types and occupations. Even to summarise the non-clinical information has been a gargantuan task, requiring over 1700 pages, descriptions of 130 antibiotics, and references to 3000 original papers and 4000 authors. The third volume, which will deal with the clinical aspects, can hardly prove a less formidable task. Knowledge in this field is now advancing so rapidly that two of the most promising antibiotics—chloramphenicol and 'Aureomycin'—have appeared since the major portion of this book was written, and only preliminary accounts of them could be included. But these volumes review the subject up to 1948 so comprehensively that they will maintain their value for many years as a secure base for further advances.

Contrary to general impressions, the study of antibacterial remedies produced by other micro-organisms did not begin in 1929, when FLEMING observed that a contaminating mould dissolved adjacent colonies of staphylococci. By that time the subject had already been studied by scientists for over sixty years. Suggestions of this type of remedy can be found in folk medicine in various parts of the world, but the first clear description of bacterial antagonism was given in 1877 by PASTEUR and JOUBERT, who found that "common bacteria" in urine prevented the growth of anthrax bacilli and suggested that therapeutic use might be made of this fact. Similar observations were made by many of the other early workers on bacteria, and technical methods were developed by GARRE in 1887 for the study of bacterial antagonism. In the early years of this century illustrations were published, indistinguishable from those that are now so familiar, of petri dishes showing the growth of one organism being inhibited by colonies of another. In 1899 EMMERICH and LÖW introduced into medicine a bactericidal preparation called "pyocyanase," prepared from *Ps. pyocyanea.* During the next ten years this was used extensively as a local application for a great variety of conditions, especially diphtheria. But its reputation exceeded its true activity and after 1914 it passed out of use. Nevertheless, bacterial antagonisms and their underlying mechanisms were still widely studied, and FLEMING's description in 1929 of the action of *Penicillium notatum,* though of outstanding importance, was paralleled by many other papers. FLEMING investigated the antibacterial properties of his crude "mould broth filtrate" in some detail, noted that it was no more toxic to animals than plain broth, and even used it as a dressing for some septic wounds; but after 1932 its further development was abandoned, apparently because the preparation was so labile. Late in 1939, work on penicillin was taken up vigorously in Oxford by CHAIN, FLOREY, and HEATLEY. The subsequent development of penicillin makes a fascinating story, chequered as it was by the disturbances of post-Dunkirk Britain and enlivened by such romantic episodes as HEATLEY driving 200 miles through a snowstorm in a borrowed van to bring back the first consignment of porcelain vessels for "large-scale" (sic) production and their first sowing with the mould on Christmas Day, 1940. The story must be read in the discoverers' own words. As late as 1943 penicillin was still described in these columns as "unequalled but unobtainable"; and it was not until June, 1946, that the development of deep-culture methods of production here and in the U.S.A. made "penicillin for all" a practical possibility. Since January, 1947, the monthly production has risen in the U.S.A. from 3 to 11 million mega units and in Great Britain from 0·25 to 2 million mega units.

Why were the innumerable studies of microbial antagonism by the earlier observers not more fruitful? It was recognised in the last century that this antagonism might be due to the secretion of specific chemical substances, and one antibiotic (mycophenolic acid) was isolated in that period. The pioneer investigators had also envisaged the therapeutic use of antibiotics. And yet they obtained no products which found a permanent place in medicine. It was partly bad luck that they did not hit upon any substances with an activity and a freedom from toxicity comparable with penicillin. But the basic cause of their failure was the lack of that liaison between biologist and chemist which is now recognised as essential for rapid progress in this field. Bacteriologists alone seldom tried to elucidate the nature of the active principles they discovered; while the antibiotics which chemists sometimes isolated were examined only superficially from a biological point of view. Moreover, antibiotics which have the greatest biological interest are usually difficult and tedious to obtain in a pure state. Work on a large scale is required to obtain enough of them for detailed examination; and such work is not usually undertaken unless there is prospect of practical—if not actually financial—returns.

The story of penicillin is an instructive illustration of the character of modern research. In the first place there is the close collaboration between bacteriologists, chemists, and many other kinds of research-workers, who confirm and amplify the original observations made in one particular field. These carry their laboratory work far enough to show that a potentially important discovery has been made; thus FLOREY and his associates established that penicillin would cure experimental infections in mice and that it had a valuable therapeutic effect in a tiny group of patients. From this point there is usually a long interval before the discovery or new remedy can be generally applied in practice—the treatment of rheumatoid arthritis with 'Cortisone' is the current example of this. The large commercial or government institutions must then be called in to help with the "development" of the discovery, and their work involves the application of as much intellectual power and far more capital expenditure than the original discovery. To American organisations goes most of the credit for the commercial development of penicillin, at a time when our British institutions were handicapped by total war. The relative costs of the two stages are illuminating. FLEMING's original work was incidental to his post as professor and a hypothetical costing might be about £500 a year. The laboratory and some of the salaries and materials of the Oxford workers were supplied by Oxford University out of its current resources, which are relatively modest, supplemented by grants from scientific bodies averaging about £4000 a year between 1940 and 1945. On the commercial development of penicillin and other antibiotics about £3,000,000 had been spent by 1946 in the United Kingdom, and over $25,000,000 in the United States. The observations and experiments of brilliant individuals have played and will continue to play an essential part in scientific progress; but the development and extension of their work calls increasingly for large teams, complex organisations, and great financial resources.

Annotations

RISKS OF ANTI-HISTAMINE PREPARATIONS

Last week we said that "several children have died from eating sugar-coated anti-histamine tablets as sweets." Apparently this is not generally known; for one writer, suggesting that the deaths we mentioned must have been outside this country, says: "The Home Office doesn't know of any. Neither does the Ministry of Health. Nor the B.M.A. Nor the manufacturers. Nor the Registrar-General's Department."[1] This is surprising, since a fatal case in the Home Counties was the subject of an inquest recently reported in the local press,[2] and another was recorded in the *British Medical Journal*.[3] In France at least three similar fatalities in children were described[4] as long ago as 1947 and objection was raised to the sale of these drugs in pharmacies without a label indicating their toxicity.

Our proposal that histamine should be used as an antidote has been challenged by several correspondents, one of whose letters we publish on p. 95.

FERTILITY AND FAMILY PLANNING

Some blame family limitation for a declining birth-rate; some assert that the decline has been, until recently, too steep to be accounted for entirely in that way. The Royal Commission on Population[5] had some reassuring things to say: first, that the main cause of the decline is certainly deliberate family limitation, and not some failure in the reproductive capacity of the nation; secondly, that though our average of 2·2 children per family will not replace the race, it comes near it, the deficiency being only about 6%; and thirdly, though in the next ten years there will be an absolute fall in the number of men between 15 and 40 years old, a small rise in family size would quickly redress this. Much of the evidence on which they based these statements was supplied by the council of the Royal College of Obstetricians and Gynæcologists, whose investigations have now been published as a separate report.[6] In the months August, 1946, to June, 1947, questionaries were completed for 11,078 married women in the general wards of hospitals. Some 3000 of them were grouped into "marriage cohorts" according to the years in which they were married, beginning with those marrying before 1910 and ending with those marrying between 1940 and 1947. The percentage using contraception rose from 15 in the "before 1910" group to 66 in those married between 1935 and 1939. After 1940 the figure fell to 55%, but this figure is certainly too low, because some of the women who had not used contraception at the time of the survey will doubtless use it later. There was a falling-off in pregnancy-rates as married life progressed, and it is noteworthy that the rates at every stage of married life were lowest in those who had never used contraceptives: in other words, many of the women in this group were subfertile. It is interesting that the pregnancy-rates after control had been tried and abandoned were "consistently and markedly higher than those of entirely uncontrolled exposure." This indicates, the report says, that "the use of birth control does not appreciably reduce the power to reproduce." Nor is the proportion of subfertile women apparently increasing. In this study, between 6·9 and 8·2% of women were "apparently non-fecund"—a proportion no greater than that (8%) of childless women married in the years round 1860.

It is rare, seemingly, for the childless woman to consult a doctor, and still rarer for her husband to seek advic on sterility. No less than 40% who did seek medic help stated that no treatment was advised. This more than unfortunate, since nowadays sterility ca often be successfully treated. Of women who ha reached the menopause, 45% said they wished they ha had more children, 9% would have liked fewer, and 43 were satisfied with the number they had. The reason given for using birth control were that more childre could not be afforded, that spacing of pregnancies wa desired, that health should be preserved, or that th parental instincts were satisfied with children alread born. This seems to bear out the finding of R. M Titmuss and others that in our society *children, unlik the tiger, do not well repay the trouble and expense* It is also clear that the expense is a far stronger deterrent to childbearing than the trouble.

VAGOTOMY FOR ULCERATIVE COLITIS

Dennis,[1] of Minneapolis, who has contributed a grea deal to the surgery of ulcerative colitis, has publishe some figures which strengthen the case for electiv ileostomy.[2] In a group of 72 patients treated medicall there was an initial mortality of over 20%; in ten year 67% were dead and of the 8 patients (11%) known t be alive only one was in good health. On the other hand in a group of 41 patients treated by ileostomy (with o without colectomy) during a twelve-year period ther was an initial mortality of 7·3%, and 75% were aliv at the end of the period. The results of ileostomy followed by colectomy were better than those o ileostomy alone.

In the last three years Dennis[3] has introduce vagotomy as a method of treatment in ulcerative colitis He decided to try this method for the following reasons (1) Vagotomy reduces bowel spasm and bowel motility (2) Engorgement of the mucosa in all parts of the bowel including the rectum, can be observed through a sigmoidoscope as a result of strong emotion, and division of the vagus nerves, by cutting off impulses from the central nervous system to the gut, abolishes this response to emotion. (3) Fatal diarrhœa, closely resembling human ulcerative colitis, is produced by excision of the prevertebral sympathetic ganglia in dogs and can be prevented by simultaneous vagotomy. Dennis claims that 22 of the first 30 patients on whom he has performed vagotomy are either symptom-free or very much improved, and his barium enema X-ray films show a striking improvement in some of the early cases.

These findings are surprising, since so far as is known the vagus supplies only the ascending colon and two-thirds of the transverse colon, the remainder of the colon and the rectum being thought to be supplied by the pelvic splanchnic nerves. It may be, of course, that this view of the nerve supply is wrong, and that the vagus *does* contribute branches to the lower colon. Or the vagi may be concerned in some other way in the pathogenesis of ulcerative colitis. In this connexion the work of Portis,[4] which was reviewed in these columns[5] not long ago, is worth recalling. He has produced evidence that emotional stimuli in the hypothalamus are conveyed by the parasympathetic nerves to the bowel, causing hypermotility of the ileum, with rapid discharge of its contents into the colon, and an over-production of lysozyme. This enzyme destroys the mucin which normally protects the colonic mucosa from the action of the digestive enzymes. Since the production of lysozyme is considerably reduced by vagotomy, this work provides an alternative or additional reason for this operation in ulcerative colitis, though Portis himself does not advocate it. It would be rational to attempt a surgical interruption of the sacral autonomic system.

Vagotomy has the attraction of sparing the patient the unpleasantness of an ileostomy. But much more work is required over a period of years before we can say whether it deserves a permanent place in the treatment of ulcerative colitis, and whether it should be used alone or in conjunction with other forms of surgery.

HOME CARE AGAIN

DOMICILIARY treatment of the infirm aged is being tried here and there in this country with success; but the pioneer of this form of care is Dr. E. M. Bluestone, director of the Montefiore Hospital, New York. In some ways the problem is different in the United States: for example, Dr. Bluestone deals with a group of patients who have no general practitioner attending them and rely entirely on his hospital. This treats long-term cases; and for many years now the approach to patients has been at once humane and scientific. The programme followed is described in a new symposium.[1]

In Dr. Bluestone's experience, patients fall into three groups: first, those who ought to have been kept in acute hospitals until treatment was complete, and who come to him, as he puts it, as "unfinished business"; secondly, patients who could be cared for at home, and who are admitted for social rather than medical reasons; and, thirdly, patients with a residual handicap, the result of a burnt-out disease, who need care either at home or in an institution. When admitted the patient is investigated and treated as fully as his condition demands; then, if he is medically suitable, and if his home conditions are approved, he is sent home and looked after by the hospital department of home care. Dr. Martin Cherkasky, executive in this department, notes that this care includes "medical service, around the clock, seven days a week." Specialists are available for the patient in the home, and such procedures as tapping and blood-transfusion are undertaken if necessary. (These advantages are, of course, at the disposal of all patients under our own National Health Service.) The Montefiore patient has in addition the help of a social worker, who visits him in his home; and of a housekeeping service provided by the hospital for 5–10 hours weekly. (In this country the health visitor and the home-help do similar work; and the district nurse gives the specialised nursing which the Montefiore patients receive from the Visiting Nurse Service of New York.) Ambulance transport to and from the hospital is provided, if the patient needs to go in again for any particular service; and any necessary equipment—such as a wheel-chair or mattress—is supplied by the hospital. A full-time occupational therapist visits him and teaches him simple activities in which he can correct faulty postures and strengthen weak muscles; usually she will get him to make small articles which can be sold to supplement his income. A physiotherapist also visits the patient at home, and any drugs he needs are provided by the hospital. It is interesting that this pattern of service has been very largely reproduced by St. Helier Hospital, with the help and coöperation of general practitioners, who supervise the patients medically, while the hospital provides equipment, physiotherapy, and transport, when necessary, to the special departments for investigation or treatment. The system has proved its value both here and in New York, and a general extension of the plan would mean better care for many of our chronic sick who are now neglected. At St. Helier the system has proved particularly useful for old rheumatic patients; but its scope is indicated by the case, described by Dr. Cherkasky, of a patient with cancer of the colon. The tumour was too far advanced to be removed, but a colostomy was done, and the patient went home with the certainty of getting nursing care, colostomy irrigations, watchful attention for complications, medication, and someone to advise on his diet. Instead of lingering, lonely and frightened, for six months, a year, or two years in a ward shared by other sick or dying people, he is at home, able to get about a bit, to take an interest in life rather than death, and to make his end in the company of people who are personally attached to him. The value of such a change can hardly be questioned, and there are no economic arguments to set against it. Indeed, a patient can be treated by the Montefiore home-care department for between a quarter and a third of the sum which would be spent in keeping him in a hospital bed.

THE CARE OF LABORATORY ANIMALS

THERE are various reasons, Major C. W. Hume says,[1] why laboratory animals may be maltreated. For example, they may belong to an unpopular species. Horses, dogs, and cats, being popular, are generally spared as much pain as possible, anyhow in Great Britain; but rats and other small animals are sometimes less considerately treated. It is possible to cite experiments done on anæsthetised dogs which have been repeated on less popular animals without anæsthesia. Then, a scientist who has to judge between the claims of his research and those of the animals he is using cannot be wholly unbiased: moreover, his training teaches him to value the well-being of patients above every other consideration, which increases his bias still further. There is a danger, too, that the necessity to inflict some pain may harden him in time, or at least blunt his sensibility towards the animals he uses, though he may be humane enough in other respects. In general, however, Major Hume finds the average biologist more, rather than less, humane than the average layman, especially about unpopular species. Finally animals occasionally come into the hands of psychopaths who derive pleasure from watching their pain. This type of cruelty may also appear in the use of far more animals than are necessary for the purpose in view.

In Great Britain animals are better protected than elsewhere, for though some other countries have laws about animal experiments, only Switzerland, Sweden, and Eire have any machinery for enforcing them. The complicated British law on the subject is summarised in the UFAW Handbook on the Care of Laboratory Animals; in practice, "a kind of traditional gentleman's agreement," Major Hume says, "has grown up between scientists and the Home Office, and though one may wish it to be improved in various ways it affords a unique degree of protection to laboratory animals." Over 90% of experiments do not involve any operation, and many produce no suffering at all. Nevertheless, some experiments induce seriously distressing symptoms; and though these probably form only a small proportion of the whole "their absolute number may nevertheless be considerable." The Home Office rule requiring that any animal suffering severe pain which is likely to endure must forthwith be painlessly killed, whether the main result of the experiment has been achieved or not, is usually well observed; but he has read some reports which made him uneasy; and some in which it was clear that the pain rule had been neglected. The four Home Office inspectors who visit the laboratories should, he points out, be able to consider experiments minutely, review precedents, and study the qualifications—humane as well as technical—of applicants for licences; but their task has outgrown their number. Experiments apart, animals may suffer from poor care and housing. Major Hume holds that the affection and care shown to animals in the animal-room will be reflected in the consideration shown to them in the laboratory. Kindly attitudes are infectious.

[1] How to Befriend Laboratory Animals. Published by the Universities Federation for Animal Welfare, 284, Regent's Park Road, Finchley, London, N.3. Pp. 16. 3*d*.

The time has come, he believes, for further advances, and those he suggests will be widely supported. In deciding whether an experiment is justifiable, the research-worker, he proposes, should ask himself: "Should I myself be willing to endure that degree of suffering *in order to attain the object in view?*" A negative answer will at once rule out painful experiments for trivial purposes. A large increase in the number of Home Office inspectors is needed, and experiments might well be classified according to their severity, licences for the most painful types being granted only exceptionally, and after elaborate inquiry. He also makes the constructive suggestion that animal-protectionists should give up the untenable position that all forms of animal experiment should be abolished, and should instead coöperate with doctors and research-workers to ensure fuller safeguards and better care for all laboratory animals. "What is needed is the frank discussion of the very difficult problems that arise, and that is impossible in the cut and thrust of controversy and mutual recrimination."

BURNS OF THE ŒSOPHAGUS

BURNING of the œsophagus by hot or corrosive fluids, if it is not rapidly fatal, may result in crippling strictures which are extremely difficult to alleviate and almost impossible to cure. Whether swallowed by accident or in attempts at suicide, the most common corrosives to cause damage are commercial solutions of caustic potash or soda, strong acids, and lysol: the less common ones include iodine, copper sulphate, and washing soda. Many of the accidental cases could be prevented by correct labelling and safe storage of dangerous liquids, and domestic laxity in this respect, especially where there are small children in the house, is often astonishing. When an alkaline or acid corrosive is swallowed the first-aid treatment is obviously neutralisation—weak vinegar for alkalis and sodium bicarbonate solution for acids—and the sooner this can be instituted the easier will be the patient's future life. Except when strong alkalis or acids have been taken (and lysol is *not* numbered among the strong acids) a very thorough and prolonged gastric lavage is then required. The acute phase of a severe œsophageal burn is fairly soon over, and patients can often swallow liquid foods in five or six days. During this interval intravenous medication will supply what is essential to life, and early gastrostomy should be avoided. Leary,[1] discussing the conservative management of these cases, recommends that at the earliest possible stage the patient should be induced to swallow a twisted silk thread which should be left in situ until swallowing is painless—a state which is often reached within a fortnight. Treatment with mercury bougies of increasing size is then started, the silk thread having ensured that the œsophageal lumen is not lost. Leary does not favour early œsophagoscopy, because he finds that it does not yield information of sufficient importance to counterbalance the risk of perforating the injured œsophagus. Mercury bouginage is repeated daily for a fortnight, and thereafter at longer intervals until it is being done once a week in the third month, twice a month in the sixth month, once a month in the ninth month, and then two or three times a year for several years. Between the subsidence of the acute phase and the onset of a stricture there is often a deceptive lull lasting some months, during which nothing is done in the belief that nothing is wrong. In fact dense collagen may be forming; only treatment which is begun early and continued without interruption will then prevent that life-long tragedy, a benign œsophageal stricture.

IN AYRSHIRE

How many hospital beds we need is still a subject for academic debate, rather like the famous controversy about angels on a needle's point. In 1948 the Nuffield Provincial Hospitals Trust, in an attempt to get some firm figures about hospital-treated sickness, reviewed the use made of hospitals by the people of Stirlingshire, and published scrupulously detailed figures.[1] In 1949 they made a companion study of conditions in Ayrshire, which they have now published.[2] The county covers 1132 square miles, has two large towns, Ayr and Kilmarnock, and in 1948 had a population of 315,500. Staffed hospital beds in the whole area then amounted to 1867 in general and special hospitals, and a further 781 in mental hospitals. Patients are treated sometimes inside and sometimes outside the county. Records were collected from 53 Scottish hospitals and 1 English hospital; and all the sick from Ayrshire during the year are thought to have been covered. They numbered 22,349 inpatients and 31,626 outpatients, plus 462 new outpatients se at venereal-disease centres in Ayr and Kilmarnoc More than 1 person in 7 of the population was treated hospital during the year. About a seventh of the 46,6 cases treated were concerned with pregnancy, childbir and its complications, and infants born in hospita Apart from pregnancy and its complications, digesti diseases were responsible for more admissions to hospita than any other disorders, and nervous and mental illness for the longest periods of hospital care. Injuries we the commonest cause of outpatient attendances. Patien most commonly sent for care outside the county we those with neoplasms, diseases of the nervous syste or injuries. The average stay of patients in Ayrshi hospitals was shorter than that of patients treate outside the county—perhaps because the severer injurie were sent to Glasgow, perhaps because local hospitals i small places can watch over their outpatients mor effectively than city hospitals.

In studying sickness in relation to social conditions, the committee used the five social groups defined by the Registrar-General. In social groups 1 and 2—those at the well-to-do end of the scale—pregnancy and its complications, and infants born in hospital, contributed more to the total of hospital-treated sickness than they did in other groups. The proportion of neoplasms was also higher in groups 1 and 2; whereas in group 5 respiratory disease and injuries were more prominent than in other groups. In general, patients in groups 1 and 2 stayed a shorter average time in hospital than patients in group 5. Where housing conditions were worst the hospital load was heaviest; and bad housing seemed to be more closely associated with some diseases than others: thus the correlation is high for infectious diseases, injuries, and circulatory diseases, and lower for neoplasms, diseases of the nervous system, genito-urinary disease, and diseases of the skin and bones.

In comparing the findings in Ayrshire with the previous findings in Stirlingshire the committee noted that the Ayrshire figures for inpatients and patient bed-days were substantially higher, but that outpatient rates were very similar in the two counties. In both, the hospital load was found to increase with the degree of overcrowding in houses in the neighbourhood. A "formidable proportion" of patients (more than half) left hospital in "less than established good health"; and the proportion transferred to convalescent homes was very low—only 0·4%.

Many additional figures are given in tables and appendices, and the report should repay close study by those who are considering our hospital-bed needs. The average reader will regret that the diligent compilers have not drawn more inferences from their findings. What must we do to be saved?

DEATH TO THE MOSQUITO

Cyprus claims to be the first endemic malarial country in the world to have freed itself from anopheline mosquitoes. Last Monday the island celebrated the successful conclusion of a three-year campaign directed to this end; and in London Mr. Arthur Creech Jones, Secretary of State for the Colonies, presided over a press conference at which the story of it was outlined.

In 1942 the incidence of malaria was 18·73 per 1000 population and the infant-mortality rate 185 per 1000 live births: by 1948 the rates had fallen to 0·87 and 67: and in 1949, of the hundred or so cases of malaria not one was a fresh infection. For the purpose of mosquito eradication Cyprus benefited by its insulation from other lands and by its comparatively small area—3500 square miles. But much of the terrain is difficult of access, and the successful outcome was, it seems, due largely to the skill and drive of Mr. Mehmed Aziz, the chief health inspector. At one time he had under his control 770 workers, using mostly D.D.T., but other agents on occasion. The cost worked out at 13*s*. per head of the population.

DISABLED MINER

Professor Browne and his associates in the Nuffield department of industrial health at King's College, Newcastle upon Tyne, record a study[1] of the first 100 patients seen in the department. These were all men, and 69 of them were coalminers. Pneumoconiosis and chronic bronchitis were the conditions diagnosed in 44, and siderosis, silicosis, pulmonary tuberculosis, and other chest conditions in a further 13. There were 15 cases of poisoning, mostly from fumes, 6 skin conditions, 6 cardiovascular disorders, 7 psychiatric cases, 2 cases of miners' nystagmus, and 7 miscellaneous conditions.

The social effect of disabling illness on these men proved to be very serious: "mining was a way of life to most of them, so that the thought of leaving it struck at the very roots of their communal existence." Dr. Browne and his colleagues found that less than 40% of the whole group were able to return to their original jobs, and only about 20% of those with chest trouble were able to do so; 27 who changed their jobs were better off than those (23) who remained idle. Seeing that men disabled by pneumoconiosis are legally debarred from working underground, it is remarkable that not one of those so disabled became preoccupied with compensation. Yet the consequences for them were very serious, for in a pit village mining is the only available work. The writers of the article suggest that more elastic legislation is needed about underground work for those who are not disabled by their pneumoconiosis; and that light industries should be established in mining areas, to offer alternative employment. Preoccupation with compensation was seen most often in patients suffering from diseases which could not be compensated. Well-meaning people—doctors among them—had often encouraged these unlucky patients to blame their work for their illness, and to fight a losing battle, "until they had become so obsessed with their grievances that they were permanently unemployable." Men with chronic bronchitis, in particular, found it hard to be told that their trouble was not caused by dust, and felt it unjust that they received no compensation, ceased to get free coal, and were not allowed to remain indefinitely in their colliery houses—privileges reserved for those with pneumoconiosis. But severe emotional disturbances of any kind were seen in only 5 men with chronic bronchitis and 1 with pneumoconiosis. "The most impressive finding was the resilience with which so many men disabled by one or other of these diseases made the best of extremely unpleasant situations."

RACIAL SUSCEPTIBILITY TO INFLUENZA

An episode related in this issue by Dr. Isaacs and his colleagues raises the question of varying racial susceptibility to attack by influenza virus. Ocean Island, one of the Gilbert group in the Pacific, is a site of phosphate mines to which come at intervals batches of labourers—either Gilbert or Ellice island natives, or Chinese from Hong-Kong. Local experience tells of attacks of influenza in the native workers following the arrival of Chinese labourers. Isaacs and his co-workers had the opportunity of studying such an outbreak, and they found that it was in truth an epidemic due to influenza-A virus.

In October, 1948, 800 Chinese labourers arrived at Ocean Island, where there were already some 300 natives—mostly Ellice Islanders. Ten days later an epidemic of influenza broke out, and it affected almost all the native men, half their womenfolk, and 10% of their children; in all there were 271 cases with 3 deaths. This group is thought to have had no previous contact with influenza, and the epidemic is what might perhaps be expected in an unsalted population. Of the 90 Europeans on the island, 12 were attacked—an incidence such as might be expected in other European communities exposed to infection. The remarkable part of the story concerns the 800 Chinese; not one was admitted to hospital, though in a number there was serological evidence of recent contact with virus A; and there was no hint of influenza on the boat during its three-week journey from Hong-Kong. Unfortunately the story does not record whether influenza had been prevalent in Hong-Kong just before the boat left, and so we cannot say whether this apparent immunity may have been due to recent experience of an outbreak. The alternative explanation merits further study. It is that here we have a racial tolerance to infection—a tolerance which permits the carrying of virus and its introduction to a more susceptible community. Such a state of affairs would be highly important to those now investigating the epidemiology of influenza on a world-wide basis.

THE HOSPITALS

The Hospitals Year Book for 1949–50 opens with an article on the first year's administration under the National Health Service.

> The regional boards, it says, have tried to steer between the twin perils of remoteness and interference, and play their part as policy-directing and coordinating authorities. But they have in fact "been pushed into a position where they are interfering unduly . . . and, what is worse, they themselves may well be subject to a greater degree of control than had been envisaged, so that there will be reached the one position which should at all costs have been avoided, where a chain of reference upwards paralyses that sense of responsibility on the part of the man on the spot which alone can ensure the full and proper development of the hospital service." The original conception was one of global budgets within whose limits the authorities immediately responsible should plan their expenditure "but we are now getting very far away from both the method and the reality."

The yearbook, now taken over by the Institute of Hospital Administrators and edited by Mr. J. F. Milne, is full of valuable information. It is obtainable from the institute at Tavistock House North, Tavistock Square, London, W.C.1, at 37*s*. 6*d*.

which made him uneasy ; and some in which it was clear that the pain rule had been neglected. The four Home Office inspectors who visit the laboratories should, he points out, be able to consider experiments minutely, review precedents, and study the qualifications—humane as well as technical—of applicants for licences ; but their task has outgrown their number. Experiments apart, animals may suffer from poor care and housing. Major Hume holds that the affection and care shown to animals in the animal-room will be reflected in the consideration shown to them in the laboratory. Kindly attitudes are infectious.

The time has come, he believes, for further advances, and those he suggests will be widely supported. In deciding whether an experiment is justifiable, the research-worker, he proposes, should ask himself: "Should I myself be willing to endure that degree of suffering *in order to attain the object in view ?*" A negative answer will at once rule out painful experiments for trivial purposes. A large increase in the number of Home Office inspectors is needed, and experiments might well be classified according to their severity, licences for the most painful types being granted only exceptionally, and after elaborate inquiry. He also makes the constructive suggestion that animal-protectionists should give up the untenable position that all forms of animal experiment should be abolished, and should instead cooperate with doctors and research-workers to ensure fuller safeguards and better care for all laboratory animals. "What is needed is the frank discussion of the very difficult problems that arise, and that is impossible in the cut and thrust of controversy and mutual recrimination."

BURNS OF THE ŒSOPHAGUS

BURNING of the œsophagus by hot or corrosive fluids, if it is not rapidly fatal, may result in crippling strictures which are extremely difficult to alleviate and almost impossible to cure. Whether swallowed by accident or in attempts at suicide, the most common corrosives to cause damage are commercial solutions of caustic potash or soda, strong acids, and lysol: the less common ones include iodine, copper sulphate, and washing soda. Many of the accidental cases could be prevented by correct labelling and safe storage of dangerous liquids, and domestic laxity in this respect, especially where there are small children in the house, is often astonishing. When an alkaline or acid corrosive is swallowed the first-aid treatment is obviously neutralisation—weak vinegar for alkalis and sodium bicarbonate solution for acids—and the sooner this can be instituted the easier will be the patient's future life. Except when strong alkalis or acids have been taken (and lysol is *not* numbered among the strong acids) a very thorough and prolonged gastric lavage is then required. The acute phase of a severe œsophageal burn is fairly soon over, and patients can often swallow liquid foods in five or six days. During this interval intravenous medication will supply what is essential to life, and early gastrostomy should be avoided. Leary,[1] discussing the conservative management of these cases, recommends that at the earliest possible stage the patient should be induced to swallow a twisted silk thread which should be left in situ until swallowing is painless—a state which is often reached within a fortnight. Treatment with mercury bougies of increasing size is then started, the silk thread having ensured that the œsophageal lumen is not lost. Leary does not favour early œsophagoscopy, because he finds that it does not yield information of sufficient importance to counterbalance the risk of perforating the injured œsophagus. Mercury bouginage is repeated daily for a fortnight, and thereafter at longer intervals until it is being done once a week in the third month, twice a month in the sixth month, once a month in the ninth month, and then two or three times a year for several years. Between the subsidence of the acute phase and the onset of a stricture there is often a deceptive lull lasting some months, during which nothing is done in the belief that nothing is wrong. In fact dense collagen may be forming ; only treatment which is begun early and continued without interruption will then prevent that life-long tragedy, a benign œsophageal stricture.

IN AYRSHIRE

How many hospital beds we need is still a subject fo academic debate, rather like the famous controversy abou angels on a needle's point. In 1948 the Nuffield Provincia Hospitals Trust, in an attempt to get some firm figure about hospital-treated sickness, reviewed the use made of hospitals by the people of Stirlingshire, and published scrupulously detailed figures.[1] In 1949 they made a companion study of conditions in Ayrshire, *which they* have now published.[2] The county covers 1132 square miles, has two large towns, Ayr and Kilmarnock, and in 1948 had a population of 315,500. Staffed hospital beds in the whole area then amounted to 1867 in general and special hospitals, and a further 781 in mental hospitals. Patients are treated sometimes inside and sometimes outside the county. Records were collected from 53 Scottish hospitals and 1 English hospital ; and all the sick from Ayrshire during the year are thought to have been covered. They numbered 22,349 inpatients and 31,626 outpatients, plus 462 *new* outpatients seen at venereal-disease centres in Ayr and Kilmarnock *More than 1 person in 7 of the population* was treated at hospital during the year. About a seventh of the 46,660 cases treated were concerned with *pregnancy, childbirth and its complications, and infants born in hospital* Apart from pregnancy and its complications, *digestive* diseases were responsible for more admissions to hospitals than any other disorders, and nervous and mental illnesses for the longest periods of hospital care. Injuries were the commonest cause of outpatient attendances. Patients most commonly sent for care outside the county were those with neoplasms, diseases of the nervous system, or injuries. The average stay of patients in Ayrshire hospitals was shorter than that of patients treated outside the county—perhaps because the severer injuries were sent to Glasgow, perhaps because local hospitals in small places can watch over their outpatients more effectively than city hospitals.

In studying sickness in relation to social conditions, the committee used the five social groups defined by the Registrar-General. In social groups 1 and 2—those at the well-to-do end of the scale—pregnancy and its complications, and infants born in hospital, contributed more to the total of hospital-treated sickness than they did in other groups. The proportion of neoplasms was also higher in groups 1 and 2 ; whereas in group 5 respiratory disease and injuries were more prominent than in other groups. In general, patients in groups 1 and 2 stayed a shorter average time in hospital than patients in group 5. Where housing conditions were worst the hospital load was heaviest ; and bad housing seemed to be more closely associated with some diseases than others: thus the correlation is high for infectious diseases, injuries, and circulatory diseases, and lower for neoplasms, diseases of the nervous system, genito-urinary disease, and diseases of the skin and bones.

In comparing the findings in Ayrshire with the previous findings in Stirlingshire the committee noted that the Ayrshire figures for inpatients and patient bed-days were substantially higher, but that outpatient rates

Staphylococcus species had been examined (after purification if necessary). Misnamed strains were translated to the correct genus and species; new strains were added to take the place of atypical strains that had been discarded and to fill gaps in the collection.

In July, 1949, the N.C.T.C. moved to a new laboratory in the grounds of the Central Public Health Laboratory at Colindale. With the additional space and apparatus available the second stage of the reorganisation began, and is now in full swing. Cultures are re-examined in detail and are dried in large numbers on a new drying plant. After drying, ampoules are opened and tested for viability, purity, and the maintenance of typical cultural characters. The specialised reference laboratories of the Public Health Laboratory Service are coöperating in this work either by supplying typical strains or by checking those dried in the collection.

When strains are examined the cultural characters are recorded on specially printed cards, and eventually the collection should be able to supply a fairly complete description of every organism in it. Attention is being directed to the cytology of bacteria, and the routine examination of a strain includes the study of its nuclear material and recording the presence or absence of septa.

COÖPERATION WITH OTHER COLLECTIONS

The N.C.T.C. has always worked in close association with collections in other parts of the world, and immediately after the late war helped to restock several collections in what had been Occupied Europe.

In 1947 a specialist conference of Commonwealth microbiologists was held in London, and the British Commonwealth Collections of Micro-organisms organisation was set up to develop culture collections in all parts of the Commonwealth.[2] The N.C.T.C. is an integral part of this organisation and is supplying cultures to the new collections established by the A.R.C. and D.S.I.R. in this country, and will send cultures that may be needed to collections in other parts of the Commonwealth.

Though direct contact with recipients of cultures is preferred, the N.C.T.C. sends cultures on behalf of the Centre de Collection de Types Microbiens to workers in Europe. However, the N.C.T.C. is not a part of this organisation and is not subsidised by UNESCO.

PROBABLE EFFECTS OF REORGANISATION

From the beginning of 1950 the N.C.T.C. will maintain and distribute only those bacteria that are likely to interest medical and veterinary workers. Workers who want other micro-organisms will have to seek them from other collections; to make this easier the N.C.T.C. will serve as a bureau of information of organisms maintained in the United Kingdom, a task which has been lightened by the publication of a directory[3] of culture collections in this country. Non-medical workers should be able to obtain more typical cultures from these specialised collections than they could in the past from the N.C.T.C., staffed mainly by medically trained bacteriologists.

Within a few months it should be possible for a worker to obtain from the N.C.T.C. carefully checked cultures of the organisms used for teaching; many of these cultures will have been authenticated by experts on the particular organisms. It is intended to issue all cultures in dried form as soon as adequate stocks have been built up. Recipients should receive their cultures by return of post, since the time needed for subcultures to grow will be eliminated.

With the continued coöperation of bacteriologists of this country the non-medical collections and the N.C.T.C. should be able to offer a much improved service.

IN A NORWEGIAN HOSPITAL

FROM A CORRESPONDENT

To be admitted to hospital the day you arrive in a foreign country might seem a depressing beginning to a holiday—and yet in fact I enjoyed the nine days I spent in the second largest hospital in Scandinavia. Everyone was kind and helpful, and it was an interesting experience to one familiar with the inside of English hospitals. In the main, of course, it was much the same—the same great ugly buildings, long, high corridors, shining chromium apparatus, and white-coated figures with stethoscopes hung round their necks. The same tests, treatment, skill, and care too—the difference lay in the small details, some important to the patient, others only noticeable because they were different.

FIRST IMPRESSIONS

I was admitted late at night, with pneumonia. From the ambulance I was taken to a bathroom on the ground floor, and there parted from my own night-clothes and inserted into hospital garments, designed with as little regard to feminine elegance as our own. They consisted of a sort of long pyjama-jacket of a smooth woollen material, with a cotton bed-jacket on top. I found them more comfortable than the cotton garments I have worn in an English hospital, because later, when I sweated my way down from 102° to a bare 99° in a few hours, they did not become cold and clammy. For a visit to the X-ray department, a pair of short trousers and a pair of long woollen bedsocks were added to the outfit, and when I was allowed out of bed I was provided with a becoming blue and white striped dressing-gown.

The second stage of my admission was a journey along a familiar type of corridor and in a familiar type of lift, after which I found myself transferred from my stretcher to a bed in a beautifully fitted treatment-room, where I was examined by a doctor on night call. When he had finished, the bed was wheeled along the corridor and into the ward. It was a comfortable bed; the main difference from an English one was that instead of blankets it had the usual Norwegian eiderdown, in a white linen cover. I found this both light and warm—it has a pleasant way of wrapping itself round one and excluding draughts—and the best thing about it was that it had a sensible pocket, nicely placed just where one's hand naturally falls, so that there was none of that searching round newly arranged pillows for an ever-disappearing handkerchief.

There were only 2 beds in the ward, and this, at least in the block to which I was admitted, was the general rule, though there were some of 3 or 4 beds, and one of 10. Double doors separated me from the corridor, almost entirely shutting out the noise and bustle which, in a ward of 30 beds inevitably goes on day and night, and which I have found nerve-racking in England. A bellcord was attached to the side of my bed, which the nurse, whose English was limited, described as my "alarm," which it certainly was: for I soon discovered that, once pressed, it continued to ring until the nurse's arrival in the ward stopped it. Sometimes I used to hear three or four of these bells ringing away together in the distance, which must have been trying for the nurses, though I never heard a complaint.

At about 10 the next morning, seven or eight white-coated figures filed into my room, and I thought that a teaching round was in progress: however these were all staff directly concerned in caring for me, who came so that they should be familiar with me and my case. There was the specialist whose bed I occupied, and his deputy, three house-physicians, one of whom was primarily in charge of me, the other two visiting me when he was off duty. There was the sister in charge of the ward and her assistant, and there was a medical clerk, carrying a great pile of documents, from which he extracted my case-history. Though I had only been admitted during the night, this was already typed and enclosed in a folder. There was also the sister in charge of administration, who visited me often afterwards and was always ready to help in any practical problem: she seemed to be half sister and half almoner. The specialist read out my case-notes to the assembled company, examined me, announced his diagnosis, and outlined the

THE NATIONAL COLLECTION OF TYPE CULTURES

S. T. Cowan
M.D. Manc., Dipl. Bact.
CURATOR OF THE COLLECTION

THE National Collection of Type Cultures was thirty years old on Jan. 1, 1950, and has just undergone a major reorganisation. So it is opportune to consider the development of the collection, to show how, as it expanded, its interests covered a wider field, and to estimate the probable effects of the changes that have taken place within the last few years.

FORMATION AND DEVELOPMENT

In the early part of this century the bacteriology department of the Lister Institute built up a small collection of bacteria that were useful for reference work; towards the end of the 1914–18 war an arrangement was made between the institute and the Medical Research Committee (later Council) to maintain and enlarge this collection for the benefit of all scientific workers. The institute agreed to provide accommodation and services, the Medical Research Council the staff and equipment. Thus, on Jan. 1, 1920, the National Collection of Type Cultures came into being, Dr. (later Sir John) Ledingham, chief bacteriologist to the institute, was honorary director, Dr. R. St. John-Brooks was curator, and Miss Mabel Rhodes was assistant curator. About 200 cultures from the institute formed the original National Collection; some of these were of historic interest and included Escherich's original strain of *Bacterium coli*, Pfeiffer's *Bacterium aerogenes*, and the type strains of *Shigella flexneri* of Andrewes and Inman.

In the early years expansion was rapid; Miss Muriel Robertson added her collection of spore-forming anaerobes, strains were received from the American Museum of Natural History (whose collection later formed the nucleus of the American Type Culture Collection), and individual workers sent strains for conservation. Originally a collection of bacteria of interest to medical workers, it was extended to non-medical fields; plant pathogens, fungi and yeasts, mostly of industrial importance, were added, and eventually outnumbered the animal pathogens. The result was that the small staff became less competent to deal with the increasing diversity of the micro-organisms in its care. Even in the 1930s it was apparent that decentralisation to specialised laboratories was needed; wood-rotting fungi, listed in the 4th edition of the N.C.T.C. catalogue, were kept at the Forest Products Research Laboratories at Princes Risborough.

MAINTENANCE OF CULTURES

In the early days all cultures were kept on nutrient media, so regular subculture was needed. The risks of loss, contamination, and replacement were great, and in 1933 experiments were made with Swift's[1] method of drying cultures. Results were not entirely satisfactory, but a few cultures dried in 1933 were viable in 1948. Professor Sordelli, of Buenos Aires, visited the collection in 1934 and described a simple method of drying cultures in vacuo over phosphorus pentoxide; this method was tried, was found satisfactory, and has been used ever since. About 80% of tubes remain viable up to twelve years; the detailed results are to be described in two papers by Miss Rhodes. Between 1935 and 1939 almost all cultures in the collection were dried in duplicate, and the amount of routine subculturing was thus greatly reduced. Cultures were not distributed in dried form, but the dried stock formed the basis of the collection.

LATER DEVELOPMENT

In September, 1939, the collection was moved from Chelsea Bridge Road to the Lister Institute's farm laboratories at Elstree. At first, with only one room available for all the work of the collection, it was fortunate that at this time the demand for cultures was much reduced. Later, benches were put up in the bathroom and a bedroom of an 18th-century house, and though these rooms were not ideal as laboratories the additional space brought relief to the scientific staff. During this period the hazards of the collection were not solely those of infection—thus on one occasion Miss Rhodes was accused of trading with the enemy because she had sent a culture to a black-listed firm in South America.

By 1944 the collection had increased to about 5000 cultures, and the work was beyond the capacity of the staff. The Medical Research Council decided that the time was ripe for a complete overhaul of the collection, that there should be greater decentralisation of cultures among specialist laboratories, and that the main emphasis should once again be on organisms of interest to medical and veterinary workers. Dr. R. St. John-Brooks retired from the curatorship in 1946, and it has been my responsibility to carry out the new policy.

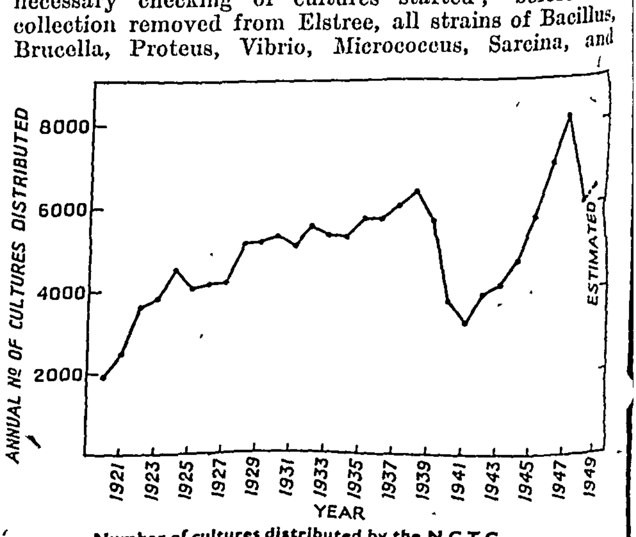
DISTRIBUTION OF CULTURES

The number of cultures distributed by the N.C.T.C. is shown in the accompanying graph; about a quarter went to laboratories outside the United Kingdom. From 1948 the collection only maintained bacteria, and the elimination of large numbers of fungus cultures formerly sent to schools produced the first reduction in activities that could not be attributed to war conditions.

REORGANISATION

In 1947 arrangements were made for the transfer of animal pathogenic fungi and yeasts to the subdepartment of mycology at the London School of Hygiene and Tropical Medicine, and of the plant pathogenic and non-pathogenic fungi to the Imperial (now Commonwealth) Mycological Institute at Kew. Non-pathogenic yeasts were sent to the Institute of Brewing in 1948. Responsibility for bacteria solely of interest to agricultural and industrial workers has been accepted by the Agricultural Research Council (A.R.C.) and the Department of Scientific and Industrial Research (D.S.I.R.) respectively; after Jan. 1, 1950, such bacteria will no longer be obtainable from the N.C.T.C.

The staff of the collection was increased and some necessary checking of cultures started; before the collection removed from Elstree, all strains of Bacillus, Brucella, Proteus, Vibrio, Micrococcus, Sarcina, and



Number of cultures distributed by the N.C.T.C.

1. Swift, H. *J. exp. Med.* 1921, 33, 69.

speak frankly and confidentially, and that her private affairs will never be laid open to discussion, however well intentioned, either in her presence or behind her back. It should therefore be arranged that when the school health visitor or the gymnast assists the doctor she should not be present throughout the entire interview. The health visitor can easily and unobtrusively occupy herself for a few moments elsewhere during some part of the examination. Thus she can busy herself obtaining some necessary details from the mother, whose attention may also need to be distracted temporarily so that the girl may have the opportunity of speaking privately to the doctor. It is important that the girl should know, like, and trust the medical officer.

Next in importance is the *mother*. The school medical inspection provides the doctor's best opportunity for educating the parent as well as the girl in the principles of physical and mental health as applied to children and adolescents. This individual teaching of the mother, no matter how brief, should be one of the chief objects of the routine school medical examination. The mother also should be given the opportunity for a few moments' private conversation with the medical officer. This can most easily be arranged while the girl is dressing and the doctor is summing up the case. Every effort should be made to secure the mother's attendance at the medical inspection. If she cannot be present, a report on a suitably designed form should be sent home. To ignore the parent's right to know the result of the interview is neither satisfactory nor courteous. Even when the girl is perfectly healthy the parent will be glad to be informed of the fact. Moreover, this note of findings and treatment advised can conveniently provide the means of establishing friendly liaison with the family doctor.

Good relations with the *school staff* are also important. All the girl's teachers are involved since each one can give the medical officer valuable information concerning the girl's health, attitudes, and abilities. The staff should be given the opportunity of reporting on the girls due for examination to the headmistress who will summarise their observations for the doctor. The sympathetic understanding and coöperation of the headmistress is therefore of paramount importance. She determines the physical environment of the examination and minimises the difficulties of premises and clerical assistance. She can influence the parents' attendance, supply the social history, explain educational problems, mitigate academic anxieties, facilitate medical treatment, and ensure a good follow-up. The medical officer should make a practice of discussing with the headmistress after each session all the findings of the medical examination which are not by their intimate nature precluded from discussion, such as illegitimacy or venereal disease. The value of these discussions is out of all proportion to the little extra time and trouble involved. The necessity for good relations with the gymnast, who will be able to report upon and treat the common postural defects of adolescence, needs no emphasis.

The *family doctor* should always be informed through the parent of any active treatment arising out of the school examination, not only to preserve good professional relationships, but also because there is otherwise a genuine risk of duplication or contradiction in treatment. This is most conveniently achieved by marking the medical report which is sent to the parent " Please show this to your family doctor." The question of his coöperation in referring problems to consultants, hospitals, and clinics also needs consideration. Difficulties arise over medical treatment, exclusion from school, permission to swim and play games, and so on, because there is no recognised machinery for friendly interchange between officials of the school health service and the general practitioner with whom the family has registered.

The experienced *school health visitor* is the doctor's most valuable asset. She prepares for the inspection and assists at it. She compiles the social history, acts as liaison officer between all the people concerned, visits the homes, follows up, and makes reports. She also plays her own part in educating the girls and the school staff. A good school health visitor can reduce the doctor's labour so that the time saved is available for conversation with the girl and instruction of the parent.

The *medical officer* should be experienced in clinical pædiatrics and in child health, and should have the opportunity of periodic hospital observation as well as public-health practice. Whether the doctor is a man or a woman does not matter very much; but it is probably easier for a woman to establish rapport with adolescent girls in the brief time allocated to each inspection. So far as possible, there should be continuity of medical care so that the visiting doctor may be able to make good personal contacts with the school and with the neighbouring practitioners and hospitals, thereby securing interchange of information in the child's interest. Experience shows that to ensure continuity of medical supervision it is best that the doctor should combine maternity and child-welfare work with school medical work. In this type of work the part-time married woman doctor can make a valuable contribution, particularly when she is young and has children. These women should be encouraged to undertake it despite any administrative difficulties.

PRACTICAL CONSIDERATIONS

Three routine medical examinations of school-children are at present required by the Ministry of Education: the first on admission; the second at 10 + on leaving the junior school; the third at 14. We do not consider three examinations are sufficient and would suggest four: at 5 years on entering the infant school; at 7 on entering the junior school; at 11 on entering the secondary school; and finally during the last 18 months—i.e., about $13^1/_2$ years—so that there is time to follow up and correct any defect found before the child leaves school at 15. In grammar schools where the girls remain longer and eventually proceed to colleges and universities, a fifth examination during the last year is desirable. All adolescents should not only have a routine chest X-ray examination before they leave school but also a Mantoux test. The importance of recording this reaction is increasing with the later age of conversion. The prospect of routine B.C.G. vaccination of negative reactors does not appear to be far distant.

Record cards are confidential documents and should never be available to scrutiny by unauthorised persons. This is particularly necessary in small communities where knowledge of the doctor's private notes could easily give rise to gossip. The new Ministry of Education form omits all reference to menstruation, although the average age of the menarche in this country is $13^1/_2$ years. This omission is serious and should be remedied. When the child enters school the maternity and child-welfare records should be passed on so that the school doctor may have the complete health picture. After leaving school the child's records should be made available to the family doctor unless they are needed for statistical survey. There is now no standard ruling concerning disposal, so all the material laboriously collected is of little practical service once the child has left school.

The conditions of examination vary widely, and medical officers are often obliged to work under conditions so adverse that much of the value of the examination is lost. It is important that the room should be warm and well lit, and that there should be facilities for handwashing. If we seem to labour the obvious, it should be remembered that some schools still lack a water-supply and artificial lighting. The room should be quiet: noisy course of treatment to be followed and the tests he wished carried out, while the house-physician in charge of me and the medical clerk took notes. While the company filed out, the specialist summoned his best English to assure me that he was satisfied and hoped to have me well in a few days. Subsequent rounds, which were usually between 10 A.M. and 11 A.M., consisted only of the deputy specialist, the house-physician, and one sister. As my recovery was rapid and uneventful, I did not see the Great Man again.

Hospital routine seemed to be much the same as at home. The usual tests were carried out, including a routine Mantoux test on admission. But it was something of a shock to be roused from the comfortable doze which follows the business of washing and bedmaking in the morning, and precedes breakfast, to find a familiar figure in a short white coat carrying a tray of test-tubes and assorted apparatus demanding my blood at 7 A.M. When I remarked that in England these things were done after breakfast, they replied with truth that by starting early it was possible to have results ready in time for the morning round.

It was noticeable throughout that pressure was far less acute than in England. Tests or special examinations were carried out within a few hours, instead of a few days. Only in the X-ray department was there the same air of stress as in England, and there I noticed a lack of adequate space and equipment, and saw a small staff struggling with too many patients in too small a space, just as they do at home.

The shortage of nurses too seemed less acute; nor did they seem so overworked. They worked one of two shifts on day-duty—either from 7 A.M. to 4 P.M., with one and a half hours off for meals during the shift; or from 4 P.M. to midnight, with the same time off. They all liked this system, because it gave them either the greatest part of the day, or the whole evening, free. Their training lasts three years, and did not seem to differ in any important respect from ours. Many of them looked forward to working in an English hospital after finishing their training. The staff of the hospital, both medical and nursing, are in the employ of the municipality.

THE PATIENT'S ROUND

My day started between 5·15 A.M. and 6·15 A.M. with the usual thermometer and basin of washing-water; but not, alas, with a cup of tea. This was perhaps what I missed most, especially during the first night, when I was fairly ill and did not sleep. Then I remembered how the weary sleepless nights in an English hospital are helped on, just when they seem interminable, by tea, hot and sweet and wonderfully comforting. Breakfast arrived at about 7.35 A.M., dinner at midday, a cup of coffee at 1.30 P.M., and high tea at 5.30 P.M. I found the food good. It was hot, pleasantly served, and quite sufficient. It seemed to me much better than that offered in a large and important London hospital where, though I was less ill, I found the food so unappetising that my small appetite evaporated and I subsisted on eggs brought by kind friends. The evening temperature, washing, and bedmaking round was at about 4.30 P.M., and the house-physician usually looked in between 6 P.M. and 7 P.M.; but this may have been to get a little practice in English conversation!

The ward cleaning was done by a woman who morning and evening swabbed over the floor with a mop and a pailful of disinfectant. The floors were of stone, so that the heavy, exhausting task of polishing a vast acreage of linoleum was avoided. The dusting was done by the nurses, but in the clean atmosphere there was wonderfully little dust, and in the absence of blankets no fluff accumulated under the beds. Visitors seemed to be allowed every afternoon.

As in England, sickness does not place a financial burden on the Norwegian family. There is compulsory sickness insurance for the lower-income group. Above this level the wage-earner pays to an insurance society a small weekly contribution which covers the whole family. After paying the expenses of an illness, the patient submits a claim and receives about nine-tenths of the amount paid.

There were no religious services in the hospital on Sunday, nor was my ward visited by a clergyman. I do not think there was a chaplain attached to the hospital; nor did I see any facilities for listening-in. One evening, however, a choir giving concerts in the town came and sang very beautifully in the corridor outside, while we listened with our double doors thrown open. On another occasion a group of students conducted a short service in the same way, dividing up to come into the wards to read the Bible and talk to such patients as wished to hear them.

I left the hospital, not only with a sense that I had been excellently cared for, but also with a feeling that I had been treated far more as a person than I was in an English hospital. It may be that because I was a foreigner they took special care to make me feel at home, but certainly I never suffered from the sense of losing my individuality which is a common sensation with patients in the larger hospitals at home. Perhaps the fact that when you first arrive each nurse and doctor introduces himself or herself and shakes you by the hand, had something to do with the feeling. It was a comforting sensation, and one which gives special warmth to the gratitude with which I shall always remember my short stay in hospital in Norway.

Public Health

SCOPE AND OPPORTUNITIES OF THE SCHOOL HEALTH SERVICE IN RELATION TO SCHOOLGIRLS

REPORT BY A COMMITTEE OF THE MEDICAL WOMEN'S FEDERATION *

THE raising of the school-leaving age to 15 has brought within the scope of the school health services almost every girl in the country at the most significant stage of her development. Moreover, now for the first time every child will be on the list of a family doctor, with whom, in her interest, friendly professional relationship should be established. Most of these girls are well grown and healthy, showing only minor defects. The school medical examination, if it is viewed solely as an occasion for finding and documenting defects, can easily become a mere routine inspection—thorough perhaps, but uninspired and leading nowhere. Obviously, however, the opportunities provided by the routine medical inspection are an important part of preventive medicine, and so far-reaching in their potential effect that this examination should be regarded rather as a survey of growth and development, with all that this implies for the girl herself, for her entire age-group, and for her future children.

PERSONAL RELATIONSHIPS

The examination time allocated to each girl can rarely exceed 10 minutes, and must sometimes be reduced to 6 or 7 minutes for the straightforward cases, to allow longer time for the more complicated ones. Re-examinations are sometimes still scheduled at 18 to the hour. Within this all too narrow space the medical officer must provide opportunity not only for the actual physical examination, but also for private interviews and discussions with the various people concerned. This economical apportioning of minutes alone demands experience and considerable skill.

The most important person is the *girl* herself. In deciding who else should or should not be present at any part of the examination—the mother, the school nurse, the headmistress, the gymnast—it is the girl's needs and susceptibilities which must be the doctor's first concern. It is essential that there should be good rapport between the medical officer and the girl. She must feel that the interview is designed for her welfare, that she is free to

In England Now

A Running Commentary by Peripatetic Correspondents

ONE of the joys of spending Christmas at home in the country is renewing acquaintance with that epidemiological horror of horrors—RAW MILK. I always suspect our producer-retailer of having had a part in my positive Mantoux test and immunity from subsequent attack by the acid-fast bacillus, so I welcome the annual opportunity of imbibing another dose of his special antigen. Incidentally, to me the taste of raw milk is exquisite.

On Boxing Day I met him with the float in which I had often ridden as a boy; but, alas, he was unshaven and had not had a good Christmas. An irritating barber's rash had made it a misery. Had he had any treatment, I inquired. He had, but he didn't make much of this penicillin cream, and it ran down his neck too. He thought the old-fashioned remedies were the best and he proposed to use one which his father had often used with a hundred per cent. success. "What is that?" I ventured. "Fresh cow-muck and home-rendered lard," said he.

I agreed that prima facie this mixture had potentialities denied to penicillin, and after an exchange of pleasantries he continued on his way. "Mind you, though," he said, half-turning in the float, "it's got to be fresh."

* * *

Talking of secretaries, in our hospital this admirable group of young ladies, is presided over by Mrs. B (the orthopod and pædiatrician), who, besides being able to concoct a coherent letter from a series of disjointed and apparently unrelated statements, can recite from memory a goodly portion of Dorland's *Medical Dictionary*. You can almost pick the specialty of each secretary at a glance, as you can at a meeting of doctors. The midder and gynæ secretary is a sleek blonde type with impeccable nylons, the medical secretary looks studious and intense, the surgical secretary is brisk and business-like, and finally we have a prosperous-looking "specials" secretary.

In spite of the stern supervision of Mrs. B, some typographical errors inevitably escape attention. So the practitioner who sent a patient to the obstetrician to diagnose a ? pregnancy was perturbed to hear that "The beasts were active. . . ." Another doctor was gratified to learn that a marasmic baby was "pale and thin and had no subcutaneous feet." The advice from the medical specialist, that "This patient is now much better and I suggest you carry on with her for three months," was, I trust, not taken too literally. The aural surgeon who saw a "bus in this man's ear" was neither intoxicated nor suffering from a delusion. And we hope the practitioner who was told that "This patient's testicle has almost disappeared" realised that "testicular swelling" was intended. In spite of their occasional lapses—which now go into a book of howlers—these young ladies, by translating into respectable English the mutterings of doctors whose accents vary from that of a Canadian backwoodsman to the polished tones of the visiting specialist from London, play an important part in keeping the N.H.S. going. Could they not be given a degree in recognition of their services—perhaps a F.F.M.S. (Fellow of the Faculty of Medical Stenographers)?

* * *

We were a small company at our hotel for Christmas—all adults except one schoolboy and four-year old Bessy. Bessy was an extreme case of long-standing adenoids, which completely blocked her upper respiratory passages, and caused considerable difficulty in swallowing. Her voice was thick and her appetite fickle; she was thin, restless, and impatient. Every meal was a struggle between her and her weary-looking mother, who incessantly entreated her "darling" to eat. Bessy won every contest hands down.

The preparations for Christmas had clearly cost Bessy's parents much toil and expense, for their main object seemed to be to give Bessy as many presents as possible. She had so many that she did not look at half of them. Her chief delight was in disturbing everyone in the hotel, so it was not long before the sitting-room was left to Bessy and her family.

A typical example of the spoilt only child, one would say. But Bessy's mother ingenuously gave us her explanation on the last morning of their stay. It appeared that at home Bessy was frequently beaten with a stick, which was laid on the table at every meal as a reminder. Over Christmas the stick had been left at home, and Bessy had seized this Heaven-sent opportunity to prove herself a problem-child of the most irresponsible and uncontrollable variety. Any one of her fellow guests would gladly have missed his Christmas dinner and made the journey to Bessy's home to fetch that stick. Which only shows how far we have to go before the troubles of childhood get considered objectively.

* * *

Whether excitement and suspense increase the secretion of urine, make the bladder intolerant of expansion, or accentuate the trigger mechanism is for the physiologists to explain. My small son only provided evidence of the excretory phase of the process at his first visit to the pantomime. On the first occasion when Nature interrupted his enjoyment Mummy was next to the gangway and the procedure followed the usual channels, though tuppence had to be thrown as a sop to Cerberus. In the second act when tension again made knocks on consciousness Daddy occupied the conductor's seat, and, despite protests, the boy was firmly led through a symmetrically placed doorway. The glistening slabs of porcelain created a bigger stir in his mind than all the gold and tinsel on the stage. Excited before, this denouement transported him to heights of ecstasy. Hurrying back with firm and manly steps, instead of subsiding into his seat with some bashfulness, as does the bridge-player, he stood on it and gave a whoop to signal his majority, during one of the few periods when the rest of the audience were quiet. He is just at the age when memory begins; what will the psychologists say if his earliest recollection is of a white urinal?

* * *

It was 2.30 on the afternoon of New Year's Day. The telephone rang. Would I go at once to Mrs. Tubb who kept urging (retching) and, the neighbour said, was like to die?

One glance at Mrs. Tubb was enough to make the diagnosis of hangover a pretty confident one. "You were at a party last night?" "Yes, doctor." "What did you have?" "Not much," interposed Mr. Tubb, "I only give 'er a coupla of beers—." "Yes, Fred, but arter you went to play cards I 'ad two more beers, three sherries, a whisky, a gin, and a drop o' brandy to top orf."

"Speaking not so much as a doctor," I said, "but with the bitter experience of a medical student, I can assure you that there is no cure for this disease. You have had the jam; now you are having the powder. Take nothing but drinks of sweetened water between now and tomorrow morning and you will be better." She was.

* * *

The misadventure to my small son when he was thrown out of our sports car at 40 m.p.h. and escaped with abrasions on his knees and one hand (*I.E.N.* Dec. 24) has had a sequel. Apparently his form-mates at school followed the progress of the grazed knees with enormous interest, which my lad stimulated by exhibiting a hand enclosed in plaster because of a chronic paronychia quite unrelated to his accident. My wife met the parents of one of his best school friends a few days ago and learned how their son, an only child, had been enthralled by the mass of bandages and plaster-of-paris. Each day he would come home and deliver a bulletin on the case. When some minor fracas developed in their home and their son was having the worst of it, he burst into tears and ejaculated between his sobs: "I'm nobody's favourite. I don't even fall out of a motor-car—I'm always too careful!"

Moral: Better a lacerating love than cold caution. (Child psychologists probably know all about this.)

school activities in the near vicinity are a serious distraction. It should be large enough for accurate vision tests to be made, and for the girl to be seen walking. Windows and glass door-panels should be curtained, and screens will also be needed to ensure privacy for undressing and during examination.

The school health visitor will start the examination by charting the height, weight, and vision, and will record as much of the history as she can obtain. The girl should strip to the waist and remove shoes and stockings. If she is obliged to wait for a few moments, she should wear her blazer. The health visitor will unobtrusively engage the girl's attention when the doctor wishes to speak privately to the mother, and vice versa. It will also be the nurse's duty to follow up the recommendations given, to report progress, and to act as liaison officer between the doctor, the school, and the home.

Although well-designed and well-equipped schools are planned for the future, many school premises at present are so defective that they are an offence against public health. We would urge the responsible authorities, in the interest of the health of the nation's children, to give the provision of civilised conditions in schools the highest priority. It is not luxury that is required, but common decency. The excuse that these buildings are intended only for temporary use is not valid. Childhood itself is temporary.

Adequate washing and toilet facilities must be provided for all children, but adolescent girls need special consideration. Means of obtaining and disposing of sanitary towels without distress or embarrassment to the girl can be devised. The lavatories should be provided with suitable bins or an incinerator out of the way of the younger children—an additional cloakroom for the older girls is very desirable. Supplies of soap, towels, and toilet-paper are essentials that are not invariably provided. A sick-room (better called a rest-room) with a couch is desirable, and to ensure adequate supervision this should be near the headmistress's room or the staff room, in preference to being a part of the sanitary unit.

We would also stress the necessity for periodic radiographic and clinical examination of staff. Women staff need facilities for their own personal hygiene,[1] and many schools are deficient in this respect.

EDUCATIONAL IMPLICATIONS

While the medical examination affords the best opportunity for instruction in the management of menstrual difficulties, there are other aspects of personal hygiene—e.g., the general principles of healthy living, cleanliness, food, fresh air, and clothing—which can most conveniently be taught in class. There are also certain delicate matters such as body odour, head lice, dirty necks, feet, and finger-nails, and soiled torn untidy clothing, which are best dealt with in groups, since each girl is less likely to imagine that she is being subjected to personal insult.

We are of the opinion that girls should receive straightforward instruction in the biological facts of reproduction from a class teacher who has some knowledge of biology. Instruction in menstrual hygiene is most suitably given by the mother, but if she lacks accurate knowledge, or does not find it easy to express herself in words, this duty may be delegated to the school health visitor. To introduce a medical officer specially for this purpose might give a suggestion of morbidity to a normal physiological process. Instruction with regard to sex behaviour is primarily the duty of the parent, but talks from an experienced doctor are often needed. These talks may be given to individuals or to groups but not as part of the routine medical examination.

The adolescent schoolgirls of today will be the wives and mothers of tomorrow, but the need to include mothercraft and domestic subjects in the curriculum of all secondary schools for girls is not always appreciated. This is particularly true of grammar schools where the study of household science is often sacrificed in favour of academic examination subjects. Since many of these clever girls will themselves become the teachers and leaders of the next generation, they should understand the dignity and social value of intelligent housekeeping.

If the girl is to appreciate the necessity for learning health, child care, and homemaking, her teacher must be adequately instructed. The subject of the training of the teacher is too vast to open here, but the person who knows most about the health of the school-child is the school medical officer, and it seems a waste of opportunity not to put this expert knowledge and skill to better use in the training of teachers.

We do not claim in this paper to have made any original contribution to the study of school health problems, but we feel, as medical women, that we have a special interest and responsibility in the health, development, and happiness of school-children and particularly of adolescent girls. We therefore offer these suggestions for consideration and discussion.

[1] 1. *Lancet*, 1949, i, 925.

Poliomyelitis in 1949

Corrected figures for poliomyelitis notifications and deaths in England and Wales during 1949 are not yet available; and in the following table, which gives poliomyelitis and polioencephalitis together, the figures for the last quarter have been estimated from the uncorrected notifications and the weekly returns of deaths in the great towns:

	1926		*1938*		*1947*		*1948*		*1949*
Notifications ..	1297*	..	1585*	..	7766†	..	1859†	..	5800‡
Rate per 100,000	3	..	4	..	18	..	4	..	13
Deaths	235	..	256	..	707	..	241	..	600‡
Rate per million	6	..	6	..	16	..	6	..	14

* Uncorrected. † Corrected. ‡ Estimated on the assumption that the ratios $\frac{\text{corrected notifications}}{\text{uncorrected notifications}}$ and de [illegible] were the same in the fourth quarter as in the third.

The epidemic of 1949 was second only to that of 1947 and considerably exceeded those of pre-war years. The years 1926 and 1938 have been included because they had the highest recorded incidences up to 1947.

As in 1947, distribution in 1949 was widespread, but in contrast to 1947 incidence was relatively high in the south-west and relatively low in the north-east.

the nature of the work to be undertaken, as Dr. Todd appears to assume. The object to be attained, especially in these days of shortage of labour, is placement; and few applicants for work are in fact rejected. It is a practice which, properly used, increases human happiness and productive efficiency. Dr. Todd does much less than justice to British industry and, it may be said, to the doctors engaged in carrying out placement medical examinations when he suggests that the information gained by these means is used in such a way that it causes "as a rule a grave interference with the liberty of the subject."

Ripley, Derby. G. F. KEATINGE.

PNEUMOCONIOSIS AFTER EXPOSURE TO SULPHUR DIOXIDE FUMES AND DUST FROM COKE FIRES

SIR,—The article by Dr. Dunner and his colleagues in the issue of Dec. 31 raises very important questions.

If the conclusions implicit in the article are valid, it would seem that 17–20% of men with respiratory disease sufficient to bring them to a chest clinic and employed in such occupations as boiler-stoking with coke, blacksmithing, gas-stoking, and the like, are suffering from industrial pneumoconiosis. These trades have a sizable proportion of the men employed in heavy industry, and it would therefore follow that there must be an immense amount of industrial pneumoconiosis undiscovered in the country as a whole—many thousands of cases and (presumably) hundreds of deaths each year. As a corollary the trades mentioned must be regarded as dangerous trades. If this were true the implications would be serious indeed.

I suggest, however, that the authors' conclusions should be taken with reserve. There are many reasons for this, of which the following may be mentioned:

1. Ten cases are hardly adequate evidence when, if the authors are right, there must be many thousands.
2. By what means was tuberculosis "excluded with certainty"? Surely the fact that a search for tubercle bacilli was unsuccessful and that there was apparently no evidence of toxæmia could not exclude the possibility that the fibrosis had been caused by tubercular infection?
3. No count of atmospheric dust appears to have been made and it would appear that the only analysis made was of a sample of dust collected from an unspecified place by a workman. Moreover, the analysis gives no indication of the proportion of the dust which was of potentially pathogenic size.
4. How many of the jobs were actually inspected and the alleged exposure confirmed?
5. In the absence of pathological evidence of any kind one would have expected some more detailed clinical evidence, such as reports on bronchograms or bronchoscopies.
6. Careful industrial-health supervision of a large number of works presumably at risk has been carried out in this undertaking, among many others, for many years, but no such cases have come to light.

It is, of course, possible that pneumoconiosis can arise in exceptional circumstances. This, however, would not explain the authors' finding that out of 50–60 men employed in the relevant trades no less than 10 were the victims of pneumoconiosis caused by their work.

I can, however, agree with the authors in their statement that more examinations of workers in these trades are needed. When adequate numbers of apparently healthy men and of men with known respiratory disease have been investigated, the matter will not be in doubt. Until then I am sure that the authors would agree that these conclusions should be taken as at most tentative.

I must make it clear that I am not writing officially on behalf of the South Eastern Gas Board but as one with some experience of this industry.

ACADEMIC SALARIES

SIR,—The implementation of Mr. Whittaker's plea last week (p. 45) that "medical" salaries should be applied only to those with definite clinical responsibility, and not to medically qualified members of other university departments, could only lead to a draining of medically qualified persons out of the pathology, bacteriology, biochemistry, physiology, anatomy, and pharmacology departments into clinical work.

Perhaps this does not alarm Mr. Whittaker. To me it is much more alarming than his fears that the paying of "medical" salaries to medically qualified persons in these departments will deter young men from entering them by a route other than that provided by a medical course, and encourage older men to waste time becoming medically qualified.

It is difficult to see why the existence of two salary scales should be held to check the development of the medical sciences. Under this arrangement the non-medically qualified scientist makes no financial sacrifice if, for example, he elects to work in a physiology department instead of a chemistry department. If the medically qualified scientist elects to work in a physiology department instead of in a clinical department, he may make a sacrifice, but it is smaller than Mr. Whittaker desires.

The main objection to the dual scales is, of course, the possibility of internal discontent within a department. At least one university has avoided this trouble by paying "medical" salaries to all members of the pre-clinical departments irrespective of medical qualifications. This has been criticised on the grounds that the non-medically qualified scientists might thereby be attracted into these departments, and diverted from work for which they have greater abilities. It might equally well be argued that the prospect of high medical salaries, against which no voice has been raised, may divert an undue number of the most able students entering a university to the faculty of medicine.

Had Mr. Whittaker extended his claim for equality at the "non-medical" level to include clinical departments, it would at least have had the merit of consistency. In the absence of such equality it is essential for medically qualified scientists to receive the same treatment as all other doctors.

While everyone will wish to acknowledge the contribution to medical teaching and research made by non-medically qualified scientists, it cannot be admitted that those who are medically qualified, a great many of whom have also a primary and higher degree in one of the physical and biological sciences, are any less able than those not so qualified to provide students with the "scientific outlook."

INFLUENCE OF HEART-RATE ON CARDIAC OUTPUT

SIR,—Your informed readers will find the answers to Dr. Plesch's letter of Dec. 31 in the article[1] which he criticises. They will understand that my colleagues paid special attention to the influence of heart-rate change on the hæmodynamic effects of digitalis. They will also be aware that there has been in this country an important school of thought, led by Mackenzie and Lewis, that the reduction of ventricular rate by digitalis in auricular fibrillation was of major importance in the production of clinical improvement.

On the technical side, Dr. Plesch lacks experience of modern laboratory work on cardiac output. His remarks on the unreliability of the Haldane blood-gas method and of spirometry are simply to be categorically denied, particularly since the introduction of the water-immersed

Letters to the Editor

ARMY MEDICINE IN THE LATE WAR

SIR,—The instalment of Dr. Todd's article published in your issue of Dec. 17 has already attracted criticism. The realisation that there was more to come prevented me from taking up the cudgels immediately, although arguments used by Dr. de Burca, Dr. Woodruff, and Dr. Dimson (Dec. 31) to refute certain of his statements I had already noted myself in considering a full-scale attack on this essentially provocative and tendentious paper.

It is true that directives on treatment always seemed to cause irritation, especially among more highly qualified and responsible medical officers. Such directives, however, were not the work of ignorant or junior staff officers, but were invariably produced by experienced consultants after full consideration and conference; moreover they were intended—at all events so far as India and Burma were concerned—not so much for the instruction of the skilled physician as to prevent inefficient treatment by the very large number of ignorant medical officers employed in the Forces at that time.

It is perhaps forgotten that in 1942 the old Indian Medical Department with its British and Indian cadres of assistant and subassistant surgeons was absorbed into the Indian Army Medical Corps, and warrant officer and Viceroy-commissioned medical officers, by the hundred, overnight became fully fledged medical officers. Change of status, however, did not mean change of capability or intellect.

The emphasis always laid on laboratory diagnosis of malaria and amœbic dysentery was, of course, intentional, and was designed to underline the essential importance of the laboratory and the clinical side-room. It in no way precluded the early treatment of "clinical" malaria or amœbiasis, both of which, in the hands of the efficient and experienced medical officer, received full recognition. Dr. Todd himself, however, has expressed horrified disapproval of prolonged retention in hospital of chronic and undiagnosed, or partially diagnosed, sick. The first essential in any approach to disease must surely be a scientific determination of its true nature, and this seldom delays the initiation of treatment. Failure to submit cases of malaria in particular to the full therapeutic course meant an enormous loss of man-power by subsequent relapses and subhealth; and for this reason, if for no other, insistence was placed on the official régime. The application of this rule in the early days of 1942 and 1943 certainly implied evacuation, often over the most difficult country and in shocking conditions, climatic and other. It was for this reason that in 1944 many of us fought so hard for the adoption of the principle of forward treatment—a principle eventually vindicated in its entirety.

Dr. Todd unfortunately has not fully grasped what is meant by forward treatment. For purposes of practical application in Assam and Burma all medical units within a corps area came to be regarded as affording this. In certain cases the regimental medical officer could hold his own sick, especially those likely to be fit for duty within two or three days; the fact that large supplies of sulphaguanidine were officially made available for use in the regimental aid post is positive evidence that such treatment was encouraged. The excellent work done by the field ambulances, with their usually capable medical staffs, has not been forgotten; and they were never discouraged from holding the sick of their own divisions in "peace-time" conditions. But when actual fighting was in hand (as it generally was) the ideal level for holding the acute or subacute medical case *with reasonable hope of early return to his unit* was the "corps medical centre," composed of one or more casualty-clearing stations and one or more malaria forward-treatment units, with ancillary services (dental, transfusion, pathological, neurosurgical, psychiatric, &c.).

It cannot be gainsaid that, right up to the end of the war, there was a certain amount of opposition to this policy. This was evidenced in many ways, perhaps most strikingly by a reluctance to provide enough nursing sisters and other female personnel, and, for a time at least, by the imposition of severe restrictions on the way in which they should be used. However, all these difficulties were very largely overcome and there is little doubt that the consequent enormous saving in man-power contributed not a little to the comparatively rapid completion of the Burma campaign. It is, therefore, with considerable resentment that one reads the concluding paragraph of Dr. Todd's second instalment (Dec. 24). In this he states:

> "In Burma . . . far greater efforts should have been made to prevent it [evacuation] from proceeding *beyond field-ambulance level* . . . air evacuation to base hospitals . . . should, in general, have been reserved for the severely wounded and those with grave diseases such as typhus fever."

To this I would reply that every possible effort was made to prevent unnecessary evacuation; that air evacuation was a help rather than a hindrance in that it made it possible to use corps medical units for retaining suitable cases and to evacuate those long-term cases which could not have withstood the rigours of ground evacuation and would otherwise have blocked the bed potential; and finally that the one category of patients never evacuated were those suffering from scrub-typhus. Bitter experience taught us that the only way to avoid a high mortality in this serious disease (which incidentally had a most profound effect on morale) was to hold cases as near as possible to the place in which they fell sick. It was directly owing to this policy that the mortality-rate from this disease was reduced to less than 10%.

In conclusion, I would register a strong protest against the all too prevalent theory that administrative medical officers were, of necessity, near-morons. As a "non-regular" administrator, I had the good fortune to come into close contact with a very large number of hard-working enthusiasts, many of whom were endowed with foresight, drive, and personality. Furthermore, our high-ranking consultants—that is to say, those responsible for technical direction—were almost without exception militarised civilians of the utmost distinction. While fully agreeing that the Army Medical Services were in many details far from perfect, I suggest that they did a magnificent job of work in all theatres of war—and one which was appreciated not only by the individual soldier, but also by all those responsible for the maintenance of morale, the control of man-power, and the furtherance of operational efficiency.

PLACEMENT MEDICAL EXAMINATIONS

SIR,—In his most interesting article concluded in your issue of Dec. 31, Dr. Todd expresses the view that "there is no real place for a medical examination as a part of the selection of adults for jobs." Elsewhere in the same paper, medical examination is clearly advocated for selecting men for training in certain occupations in the Services; consideration, it is stated, should be given to "separate bodily functions."

It is hard to see why the same procedure should be denied to workers in civil life. It is disappointing for the trainee and expensive for the employer if bitter experience is to be the only test of a person's fitness for undertaking work requiring, say, high visual efficiency. However this may be, medical examination in industry is not as a rule based on a rigid standard of fitness unrelated to pressure is to fill shallow domestic baking-trays with talcum, wrap in brown kraft paper, and then sterilise by dry heat in an oven, allowing sufficient time for the whole of the contents to be at 150°C for at least two hours.

One practice I have met which is particularly undesirable consists in putting up a relatively large quantity of unsterile talcum (up to 25 g.) in a gauze bag; one such bag is then placed inside each pair of gloves, with the idea that it can be repeatedly used and resterilised, thus avoiding the labour of refilling each time. It is permissible, however, to use very small quantities of talcum in gauze folders packed inside the cuffs of gloves.

Dr. Sevitt mentions the desirability of ensuring the easy entry of "superheated steam" when he presumably means "saturated steam," which is a better sterilising agent.[10] His excellent article emphasises once again the necessity for all sterilising processes to be supervised by responsible and trained personnel. In this connexion I have found Carl Walter's textbook[9] invaluable.

Hertford. JOHN C. H. HANSON.

GRAPHITE PNEUMOCONIOSIS

SIR,—In his comments on my letter of Nov. 19, Dr. Dunner (Dec. 3) claims to refute the possibility of an infective origin for massive lesions in graphite pneumoconiosis, on the basis of his clinical and radiological findings in 9 cases (so far as I can determine from his articles), including post-mortem observations on one of them.

I agree with Dr. Dunner that the "miliary snowstorm" appearance on the X-ray film probably reflects the changes produced by dust alone, but because massive shadows sometimes develop subsequently to the miliary ones it does not necessarily follow that the massive fibrosis represents a later stage in the development of the focal dust lesions. The results of radiological investigations into coal-workers' pneumoconiosis show that large localised shadows, representing massive lesions, quite commonly develop in cases showing the generalised X-ray appearances known to result from simple pneumoconiosis; and the conclusion of Davies et al.[11] favours the view that such massive shadows are infective in nature and often tuberculous. Dr. Dunner's cases follow a similar radiological course and hence on this ground the infective origin of massive shadows in graphite workers cannot be lightly dismissed.

For the pathological and bacteriological reasons previously given, there is justification in the case of coal workers for regarding massive fibrosis as the result of another disease process superimposed on the purely dust lesions. All the available evidence points to the added process being infective and often this is clearly tuberculous. Even in the absence of specific evidence of tuberculosis, the general pathological appearances of massive lesions are so consistent as to suggest that the pathogenesis is fundamentally similar in all cases. It may well be that in some cases the infection is ultimately overcome, just as occurs in uncomplicated tuberculosis. Although the operation of some other infection than tuberculosis cannot be excluded, this appears to me unlikely. From the pathological evidence in graphite workers provided by Gloyne et al.,[12] Harding and Oliver,[13] and Dr. Dunner, as well as from a case personally observed, there is a close correspondence between the disease in these workers and that in coal workers, and hence the distinction between infective and simple dust lesions also appears applicable to graphite pneumoconiosis. Post-mortem study directed to the isolation of the tubercle bacillus from massive lesions in graphite pneumoconiosis is a prime requirement, of which as yet I know no record.

It is known that in coal workers tubercle bacilli occur much less frequently in the sputum than in the lesions post mortem.[14] Thus in this connexion clinical evidence is not as reliable as post-mortem evidence. Dr. Dunner's failure to find tubercle bacilli in the sputum of one or two of his cases is therefore not surprising.

Dr. Dunner is right in demanding prolonged animal experiments to assist in deciding the rôles of graphite dust and infection in the genesis of pulmonary disease. As graphite and coal dust are not very dissimilar in their silica contents, my experience in connexion with the inhalation of airborne coal dust by rabbits underground for over $3^1/_2$ years is relevant. Massive fibrosis of the lungs does not occur, but focal dust lesions with very little tissue reaction do develop. This is quite a different type of response to that induced by the inhalation of silica dust.

The purpose of my former letter was to draw attention to an alternative interpretation of the pathogenesis of graphite pneumoconiosis to that put forward by other investigators. In this department over 700 autopsies have now been performed on coal workers from many of whom X-ray films are available.[15] When therefore another industrial dust hazard is found to produce very similar radiological and pathological appearances in the lungs, there is good reason for considering the possibility that its pathogenesis resembles that now believed to operate in coal workers.

PRINCESS TSAHAI MEMORIAL HOSPITAL

SIR,—I was delighted to observe the support for Lord Winster's appeal on behalf of this hospital which Dr. Goodman gave in his letter of Dec. 31. I am glad to observe his testimony that there is no doubt of the potential value of the hospital, "especially as a training centre for nurses." I cannot, however, concur in his suggestion that the scheme should be abandoned unless the hospital is opened forthwith.

Four years is a long time to wait; yet the period is not very long for carrying through so important and ambitious a scheme as a hospital involving the raising of £100,000 by purely voluntary subscriptions. I observe that even in pre-war days an offer of £60,000 for an annexe to one of our great British hospitals was made on the condition that a further £60,000 was raised by voluntary subscriptions within five years. That was for a British hospital; the sum which had to be collected in easier times than these was considerably less than £100,000. The council of the Princess Tsahai Memorial Hospital has had to contend with very difficult circumstances in raising funds in Britain; in the first instance, the competing claims of a host of war charities for countries in which the war was still being actively waged, whereas in Ethiopia the war had ceased; then the very heavy cost of paying for the war, which has fallen to so disproportionate an extent on the shoulders of the people of Britain.

Our council appreciates to the full the sums which have been contributed towards the hospital fund in Ethiopia, but Dr. Goodman is in error in describing these as coming solely from the British and Ethiopian communities. The Greeks, the Armenians, and the Indians have contributed very substantial sums, and of course the Ethiopians themselves, including His Imperial Majesty, who has given very substantially, as well as providing the site and the partly constructed building.

My knowledge of the sources of the large contributions to the fund which have been raised and expended on the building itself in Ethiopia is by no means complete, but so far as that knowledge goes it would appear that the non-British communities have taken the lead in this matter inside Ethiopia.

Haldane apparatus. He seems to imagine that the cardiac catheter is a coiled spring resisting the contractions of the heart. It is, in fact, flexible and imposes no mechanical obstacle. Incidentally, Starling's law is quite different from the "all-or-nothing" principle.

Dr. Plesch seems to "know" that cardiac output averages 4 litres per minute, and has apparently been satisfied with this figure since 1909. He sees no reason to change his mind either on the average figure (which is over 5 litres per minute) or on the possible range in health and disease. "It was not to be expected that drugs should influence the minute volume . . ." We regret that this satisfying thought is not in keeping with the many facts now adduced by numerous investigators using similar methods to our own in different parts of the world. Digitalis bodies either relieve venous congestion, or increase the resting cardiac output, or both, in those cases of cardiac failure which make a favourable clinical response.

The manner in which digitalis brings about relief is surely a matter worthy of serious study and research effort. In view of past speculations on the influence of heart-rate in producing clinical improvement, the investigations of Kelly and Bayliss seem well worth while. We welcome any helpful and constructive commentary, but we hestitate to reply to sarcasm and ill-informed criticism.

HÆMOLYTIC EFFECTS OF MYANESIN

SIR,—Intravascular hæmolysis after intravenous administration of 'Myanesin' has lately been discussed by Clendon and Penfold.[1]

The hæmolytic action of myanesin is the same in vivo and in vitro: concentrations greater than about 1 in 100 will cause hæmolysis within a few minutes. The occurrence of intravascular hæmolysis after intravenous injection depends on the concentration of the solution used, on the presence of other hæmolytic agents used as solvents (such as ethanol), and on the rate of injection. It is independent of the total amount of myanesin injected. Thus Zamboni and Gori[2] showed that a 10% solution of myanesin in 20% sodium hippurate (which by itself is not hæmolytic) may produce hæmaturia in doses of 40 mg. per kg. body-weight, whereas a 0·5% solution of myanesin in saline solution did not cause hæmolysis even at dose-levels of 150 mg. per kg. Both solutions were injected into rabbits at the rate of 30 mg. per kg. per minute.

I do not know of any evidence for the view[1] that serious hæmolysis is more likely with larger doses of myanesin. It is possible to inject considerable amounts of myanesin intravenously without causing hæmolysis, as has been observed by Davison[3] and others, provided that injection is carried out slowly enough to keep the concentration of myanesin in the blood below the critical level. The contention that hæmolysis and hæmaturia depend on the concentration of myanesin in the blood, and not on the total amount of myanesin given, is further supported by the absence of hæmoglobinuria and hæmaturia after the administration of very large oral doses of myanesin.[4] After oral administration, absorption is gradual and for this reason hæmolytic levels are not reached.

Schlesinger et al.[5] have shown that intravenous administration of 2% solutions of the drug is safe and does not cause hæmolysis. The intravenous use of more concentrated solutions is potentially dangerous and should be avoided. The intravenous infusion of a larg volume of a dilute solution of the drug is, of course, nuisance, but it is worth trying in strychnine poisonin status epilepticus, and certain cases of tetanus. Ofte the same therapeutic results can be achieved by th intramuscular or oral route, by which large amounts the drug can be given with relative safety.

Wyngaarden et al.[6] have shown in dogs that a 10 solution of myanesin in 40% aqueous propylene glyc does not produce hæmolysis when given intramuscular in doses up to 25 mg. per kg. body-weight. I hav given many intramuscular injections of myanesin, usin 10% of the drug in an aqueous solution containing 6% ethanol and 6% propylene glycol. This solution require warming to body-temperature before administration, t dissolve this amount of myanesin. Hæmaturia has neve been observed; the drug is readily absorbed from th muscle, and the injection is not painful. In many instances oral administration suffices, as has been shown by Godman and Adriani,[7] who were able to control satisfactorily seven cases of tetanus in children by the oral administration of the drug.

Ginzel et al.[8] observed that the *o*-methoxypheny ether of glycerol had only one-quarter of the hæmolyti action of myanesin. This congener had about one-hal the activity of myanesin. These findings indicate that i should be possible to find a soluble myanesin-like compound which would have negligible hæmolytic propertie and would be suitable for intravenous administratio Until such a compound is found, it would be advisable t limit the use of myanesin to the oral and intramuscula routes of administration.

New Brunswick, New Jersey.

F. M. BERGER.

STEAM STERILISATION

SIR,—Dr. Sevitt, in his article of Dec. 10, has made notable contribution to the study of maintaining asepsi in surgical treatment. His comments on the sterilisatio of talcum powder and surgeons' gloves prompt me t offer some views of my own which are the result o investigations in this field. It is perhaps best to begi with a statement of first principles:

1. Efficient sterilisation by steam depends upon effectua clearance of air from the autoclave chamber and from the materials being processed. To confirm this there should be a thermometer, or, better still, a recording thermograph in a condensate drain leading from the lowest point in the chamber.
2. All sterilisation processes should be subjected to bacteriological checks. A suitable method, using a standardised earth, is described by Ecker.[9]
3. It is particularly difficult to ensure clearance of air from rubber articles since folds and wrinkles may retain pockets of air. I have found a great variety of drums in use for sterilising gloves. Many have definitely hindered the clearance of air, and there is a tendency to pack in as many pairs of gloves as possible. If drums have perforations in the sides, it is essential to place them on their sides for sterilising, otherwise there may be a pocket of air trapped in the bottom of the drum. The British Standards Institution will be doing a useful service if it sponsors a standard glove-drum, which should bear a statement of the maximum load of gloves and an indication of how it should be placed in the autoclave.
4. To assist in air clearance, the upper portion of the autoclave should be used for gloves and other articles which are to be sterilised at relatively low temperatures and steam-pressures.
5. It is desirable, as Dr. Sevitt points out, to use sterilised talcum powder for dusting gloves and other rubber articles which are to be subjected to reduced sterilisation procedures. An alternative to his suggestion of autoclaving at 20 lb.

children received their course of penicillin in the same hospital and at about the same time.

The circumstantial evidence in all cases is, I feel, in favour of the lesions being produced by the introduction of tubercle bacilli at the time of the penicillin injections; but it must be emphasised that we have no definite proof of this. For the reasons already stated it has not been possible to investigate fully the details of the penicillin injection technique. It is clear that the penicillin may be contaminated at any time between preparation and injection. Apart from careful control in the preparation of the penicillin solution in the hospital, I would like to make a further plea for a general improvement in syringe sterilisation technique, which, I feel, is far from satisfactory in many institutions and has probably played a large part in producing the lesions described in this letter.

I should be most interested to know whether others are coming across this most unfortunate but highly important complication of penicillin therapy.

Royal Hospital for Sick Children, Edinburgh. DONALD M. DOUGLAS.

RELIEF IN RHEUMATOID ARTHRITIS

SIR,—Professor Spies and Dr. Stone, in their article last week, tell of water retention with improvement in joint conditions and diuresis with relapse.

Twelve years ago, while doing a "locum" in Norfolk, I had a patient, an elderly woman, with rheumatoid arthritis of the "don't-touch-the-bed" type. She had had one kidney removed for stone, and during my tenency the sole ureter was blocked by a stone for three or four days, with complete anuria. During this time she lost her pain, got back some movement, and—what amazed me, expecting uræmia—became almost cheerful. After she had passed the stone the old symptoms returned. I gathered from Dr. Harrison, of North Elmham, whose work I was doing, that this sequence had occurred several times.

It would seem possible that in the chain of causation between the injecting of adrenocorticotropic hormone and the loss of pain, fluid retention is a link—and might be a short-cut.

Beckley, Rye. C. G. LEAROYD.

PERAXILLARY APPROACH TO THE STELLATE AND UPPER THORACIC SYMPATHETIC GANGLIA

SIR,—I read with interest Mr. Atkins's description (Dec. 17) of the peraxillary approach suggested to him by Professor Goetz. I have used this approach on several occasions but I have now abandoned it for the following reasons:

1. The skin in the axilla does not seem to heal nicely and has left prominent and rather ugly scars in my cases (see picture), whereas a scar over the lower part of the neck anteriorly usually heals almost invisibly if the platysma is sutured and if the skin sutures are removed very early.

2. If a strictly preganglionic section is done via the axillary route, it is impossible to suture the upper chain in such a position that regeneration cannot occur—with the anterior approach this may be avoided by stitching the upper chain into the substance of the scalenus anterior.

3. Should the superior intercostal artery be damaged during operation by the axillary approach, an embarrassing situation would arise. It would be impossible to tie the vessel through the small incision in the chest wall, working at a depth of four or five inches. The diathermy current might be used, but the superior intercostal artery is often quite large and hæmorrhage from it is alarming. Operating by the anterior route it is wise to tie the superior intercostal artery at its origin from the first part of the subclavian artery, or the costocervical trunk. Even if this important step is not taken and the vessel is damaged over the neck of the first or second ribs, hæmorrhage can be well controlled by firm gauze packing for ten minutes or so, after which it can be easily secured.

Having tried all three approaches, my own preference is for the anterior route. I cannot agree that it is not always possible to divide the chain below the third thoracic ganglion. In one of my patients I made an anterior approach on one side and an axillary approach on the other side, and the patient was quite definite that she preferred the former. With the axillary approach I have noticed more than once a rather trying, though temporary, postoperative intercostal pain.

Hammersmith Hospital, London, W.12. PETER MARTIN.

SIR,—Mr. Atkins's letter is interesting, not alone as a clear technical exposition, but because it demonstrates the dissatisfaction frequently experienced when either the anterior supraclavicular or the posterior approach is used for upper-limb sympathectomy.

I agree with the objections instanced by Mr. Atkins, and I should like further to add that if intradural section of the associated intercostal nerves is considered necessary it can be done only with much trauma by the posterior approach, and not at all if the anterior supraclavicular approach is employed. In short, the anterior approach is nice but not enough, and the posterior is enough but not nice.

The Goetz approach, as described by Mr. Atkins, is undoubtedly a workmanlike job, and an improvement except that it is a transpleural procedure, in which respect it is, I think, objectionable. Operations, which may be prolonged and which may cut small blood-vessels, particularly if ganglionic root-section is performed, are, in my opinion, better performed by an extrapleural procedure if at all possible.

Attracted by this possibility, during the last year I denervated the upper limb by the anterior infraclavicular approach recommended to me by Prof. A. K. Henry and published by him last autumn.[1] The view is excellent, both for the chain and the blood-vessels; and as any one can see by consulting his account, an exceptional view of the dorsal-root ganglia can readily be obtained. My only objection to this anteromedial approach has been a marked tendency to rupture the pleura when reflecting it from the mediastinum, particularly in the elderly. This has stimulated me to approach the chain by an extrapleural anterolateral method which I find most satisfactory. When the chain is reached the further procedure is in general similar to that advocated by Professor Henry. At the risk of adding unduly to the methods, I shall describe it very briefly.

With the patient in the position described by Mr. Atkins, I make a slightly curved incision from near the inferior scapular angle to within 2 in. of the third dorsal spine. Some of the fibres of the trapezius and the scapular slip of the latissimus are cut, the rhomboids are split, and the third rib identified and removed from the posterior axillary line almost to its neck. A finger opens up the extrapleural space back along the line of the third rib, and gradually enlarges the space so that the hand can slip in and depress the pleural dome, which can be done from behind with great ease and with little danger of pleural rupture. Any surgeons who have watched the operation in progress have remarked on the directness and adequacy of view. Any of the approved techniques—stellectomy, excision or isolation of second and third dorsal sympathetic ganglia, with or without associated somatic nerve section, or indeed section of the sympathetic chain

---

[1] Garry, T. P., Henry, A. K. *Irish J. med. Sci.* October, 1949 p. 757.

In this country, there has been a valiant British effort, and valiant efforts are still being made, but suggestions that the scheme should be abandoned for any consideration are by no means helpful.

Dr. Goodman refers to the Russian hospital; but the Russian contribution came from the Russian Government, and was not raised by private subscription. The memorial hospital council in Britain has had no Government grant. Her Majesty the Queen early signified her sympathy by a gracious donation of £100; but it was not until 1948, when the proceeds of B.B.C. appeals had greatly diminished owing to the heavy taxation now borne by the British people, that an appeal for the Princess Tsahai Memorial Hospital was broadcast as the "Week's Good Cause."

In the spring of last year the council was led to hope that £10,000 which was collected by the late Dr. John Melly for medical work in Ethiopia, and is now in the keeping of the British Red Cross Society, would be granted to the hospital. This would have enabled the council to proceed with the remaining purchases, and to open the hospital as soon as the interior finishings and the fitting of the equipment are complete. Unfortunately, this hope has been deferred. The harder way of raising the fund pound by pound, shilling by shilling, must proceed.

Apart from the raising of funds, it has taken approximately three years after the orders were placed to secure delivery of the electrical equipment made for the hospital in this country. As the equipment is paid for in this country, it does not receive the facilities granted to dollar-earning goods.

For the comfort and encouragement of the many who have generously contributed to the memorial hospital fund, and all who desire it to be opened at an early date, I would add that though approximately £15,000 is required to complete the scheme, £5000 would enable the hospital to be opened. My appeal to Dr. Goodman, and all who desire the early success of the effort, is for cheerfulness and confidence in the project, and practical assistance to "see it through." Practical assistance at the present stage involves donations, which will be gratefully acknowledged by the hon. treasurers, Lord Horder and Lord Amulree, c/o Messrs. Gould & Prideaux, 88, Bishopsgate, London, E.C.2.

3, Charteris Road,
Woodford Green, Essex.

E. SYLVIA PANKHURST
Hon. Secretary.

THERAPEUTIC INTERCOSTAL BLOCK

SIR,—In these days, when therapeutic blocks form part of an anæsthetist's routine work, the following case-report may be of some interest.

A man, aged 69, with a history of chronic bronchitis, pleurisy, emphysema, and secondary cardiac failure was referred to our nerve-block clinic because of intractable pain along his right costal margin following a fall from his bicycle twelve months previously. He was ambulatory and had a good colour, and there was no dyspnœa at rest. There was, however, some œdema round his ankles with pitting on pressure. His chest was clinically clear, and on Aug. 31, 1949, radiographs revealed a normal diaphragm, no cardiac enlargement, clear lung-fields, and no bony injury.

On Sept. 7 a block of the 8th–12th right intercostal nerves was performed in the posterior axillary line; 'Proctocaine' 10 ml. was used for each nerve. The patient complained of no symptoms and showed no signs of distress during any of the injections, and at the end volunteered that his pain had gone. He was transferred on a theatre-trolley to the recovery-room and was told he could get dressed in a few minutes if he continued to feel all right. Shortly afterwards, however, he became cyanosed and dyspnœic with some bronchospasm and pain in the right lower chest on inspiration. Oxygen was administered, and an hour later he was referred to the X-ray department where a radiograph of the chest revealed evidence of a small effusion on the right side and some generalised hyperæmia in the lungs, particularly at the right base. There was no evidence of pneumothorax.

He was admitted to the ward, where oxygen therapy was continued. Penicillin was administered, and heroin, adrenaline, and ephedrine were given to relieve his pain and bronchospasm. Two days later, on Sept. 9, he developed severe pain in the right side of his chest and collapsed. The following day he coughed up some blood, was distressed and slightly pyrexial, and had well-marked tachycardia. There was a gross pleural rub on the right side suggesting a pulmonary infarct. On Sept. 11 a further radiograph showed that the diaphragm was flattened; there was evidence of pleurisy, but the congestive changes had improved.

He was discharged on Sept. 15, symptom-free and radiographically clear except for a small amount of fluid in the right costophrenic angle.

Normally, when performing an intercostal block on the conscious or unconscious patient, if the needle penetrates the pleura a warning cough is elicited, and, as a rule, provided that the needle is of small bore and aseptic precautions have been taken, no harm results. It would seem that in the aged, and particularly those with a history of chronic bronchitis, pleurisy, and emphysema, no warning signals are to be expected; and the anæsthetist must exercise greater caution in performing intercostal blocks on these cases, especially when proctocaine is used.

Scunthorpe, Lincs. W. N. ROLLASON.

TUBERCULOUS ABSCESS AT SITE OF PENICILLIN INJECTIONS

SIR,—Elek[1] believes that the appearance of tuberculous abscesses at the site of penicillin injections is by no means so rare as the paucity of reported cases may suggest. I feel sure that he is right. I have to hand the records of nine children, who for one reason or another were given soluble penicillin intramuscularly at some period during the last 2 years, and who subsequently developed tuberculous abscesses at the site of the injections. As none of them were under my care at the time the penicillin was given (they had been treated in a number of different hospitals), the difficulty in reporting them in full will be appreciated; and it may be that others have been presented with the same problem!

My series comprises children varying from the age of 1 month to 7 years at the time of the penicillin injections. In all cases soluble penicillin had been given intramuscularly. In five cases solitary abscesses appeared 5–7 weeks after the completion of the penicillin course; in four cases multiple abscesses appeared 6–18 weeks afterwards. In all cases tubercle bacilli were isolated from the lesions. In no case was there a history of contact with tuberculosis. In no case was evidence found of tuberculosis elsewhere in the body at the time the abscesses were first noted. In those cases in which a single abscess occurred the regional lymph-glands were much enlarged, but this was not so in the cases with multiple abscesses. Unfortunately, Mantoux reactions had not been carried out before the penicillin courses were given, but they were all positive by the time the abscesses were diagnosed. One child died of miliary tuberculosis. Six have chronically discharging ulcers or sinuses. Two were treated by radical excision of all the abscesses as soon as the diagnosis was made, and these children have done well. (The regional lymph-glands in these two cases were apparently not involved.) I am convinced that in early cases this is the treatment of choice.

The ætiology has been discussed by Ebrill and Elek,[2] Hounslow,[3] Hindenach,[4] and Forbes and Strange.[5] The five cases with solitary abscesses in this series which had enlarged regional lymph-nodes suggest at once that primary tuberculous complexes had been produced, and this is supported by the fact that one of these children was only 2 months old when the tuberculous lesion first appeared. The four cases with multiple abscesses and no lymph-gland enlargement looked clinically less like primary lesions, but it so happened that these

ble to wash and feed himself for the next five days; he received crystalline penicillin G and heparin in saline two bottles every 24 hours), each bottle being separately buffered with phosphate to a pH of about 7·2. Even so, the vein thrombosed after five days and was red and tender. In fact, in all cases where this method has been used during the past eighteen months, my longest record has been only eight days for one vein, no matter what the fluid administered or what the rate of flow. The shortest periods were with glucose-saline and a slow rate.

I understand that more satisfactory results than this are being achieved elsewhere, and especially in America, and that intravenous drips through plastic tubing can continue for several weeks at a time. I would be very interested to hear from anyone who has had more success than I. Nevertheless, I shall continue to use this method in selected cases, since I feel that an average duration of even five or six days is an advance, and the lack of splintage pleases patient and nursing staff alike.

RISKS OF ANTI-HISTAMINE MEDICATION

SIR,—Your leading article of Jan. 7 says: "In cases of acute poisoning by anti-histamines the obvious antidote is histamine acid phosphate, injected subcutaneously in doses of 0·1 mg. per kg. of body-weight." It is generally held, however, that the anti-histamines do not antagonise histamine by combining with it chemically or by inducing opposite pharmacological responses, as does adrenaline. The most widely accepted view of the action of these drugs is that they block histamine receptors in the tissues. Moreover, the side-effects of the anti-histamines, such as drowsiness and giddiness, seem to be due to a mechanism other than the histamine-receptor blocking one. Burn[1] has pointed out that the anti-histamines have properties in common with spasmolytics like 'Trasentin' and 'Syntropan,' analgesics like pethidine and papaverine, and local anæsthetics like procaine and atropine-like substances. It therefore seems doubtful whether histamine can be effective in anti-histamine overdosage. In some people, notably asthmatics, even though they were saturated with an anti-histamine, it is possible that injections of histamine would produce severe reactions.

Parke, Davis & Co.,
Hounslow.

J. STANLEY WHITE.

Obituary

HENRY CORSI

M.A., M.B. CAMB., F.R.C.S.

Mr. Henry Corsi, physician to St. John's Hospital for skin diseases, London, died in Switzerland on Jan. 1 at the age of 56.

He came to medicine by way of Uppingham and Pembroke College, Cambridge, qualifying from St. Bartholomew's Hospital in 1918. For a time he toyed with the idea of becoming a surgeon and in 1921 he took the F.R.C.S. But he soon decided that the study and practice of skin diseases was his particular bent. He served his apprenticeship with Dr. H. G. Adamson and he was for many years chief assistant in the skin department at St. Bartholomew's, where he was a well-known figure. Later he joined the staff of St. John's Hospital and he probably regarded this hospital as his professional home, for when a few years ago, dogged by ill health after a motor accident, he gave up his other appointments, he retained this one and the presidency of the St. John's Hospital Dermatological Association. At the last annual dinner of the association he was in his element, and made one of his delightful after-dinner speeches.

He was assiduous in his attendances at the meetings of the British Association of Dermatology and the skin section of the Royal Society of Medicine where anything he had to say was always well worth listening to. He was a sound teacher and ever ready to help his juniors. Also an expert venereologist he was for many years a surgeon to the London Lock Hospital, where his great natural sympathy, kindness, and understanding of human nature stood him in good stead.

J. L. F. writes: "Although not a researcher Corsi became one of the soundest of dermatologists, for he had an inquiring and original mind and never accepted any new-fangled methods until he had thoroughly tested them. In an age of stunts it was his lot to do a great deal of debunking. A fine linguist it delighted him to talk to patients from foreign lands in their native tongues. He was a good and keen bridge-player and as a host he was without equal, as those who were guests of 'Our Whist Club' when it met at his house in Harley Street will readily testify. We shall miss Henry Corsi very much."

JOHN SPENCE LAW

M.B. EDIN.

Dr. J. Spence Law, who died in Norwich on Dec. 23, at the age of 86, was for over 25 years assistant medical officer and deputy superintendent at St. Andrew's Mental Hospital, Thorpe, Norwich.

He was educated at Dumfries Academy, where James Barrie was a fellow scholar, and in 1883 he graduated M.B. at the University of Edinburgh. Before settling in Norfolk he had held appointments at the North Riding Asylum at York and at the Borough Asylum, Birmingham. When the War Office took over St. Andrew's Hospital during the 1914–18 war he held the rank of major in the R.A.M.C. After his retirement in 1919 he lived at Lowestoft, where he was a member of the Royal Norfolk and Suffolk Yacht Club. An enthusiastic bridge-player, he also used to take an active part in all outdoor sport, and he was specially interested in both cricket and golf. In his early days at St. Andrew's Hospital he kept goal for the Thorpe football club. Till 1939, he enjoyed a yearly holiday in Italy.

C. N. writes: "During the whole of his time as resident Spence Law worked under David Thomson, and he acquired an excellent knowledge in his own specialty of mental diseases. His shrewd common sense enabled him to deal satisfactorily with all types of cases, and he was never at a loss to know how to act in any emergency. He could always be relied on to do his best for any patient entrusted to his care."

Births, Marriages, and Deaths

BIRTHS

ATHERTON.—On Nov. 30, at Durham, the wife of Dr. R. A. Atherton—a daughter.

COSH.—On Jan. 2, at Bristol, the wife of Dr. John Cosh—a son.

COX.—On Jan. 2, the wife of Dr. Michael Cox—a son.

FOWLER.—On Dec. 23, in London, the wife of Dr. P. B. S. Fowler—a daughter.

INGHAM.—On Jan. 1, wife of Major F. J. Ingham, R.A.M.C.—a son.

JAMES.—On Dec. 31, in Birmingham, the wife of Dr. A. R. James—twin sons.

LUNT.—On Jan. 4, in Manchester, the wife of Dr. Reginald Lunt—a son.

SHEILD.—On Dec. 19, in Singapore, the wife of Mr. A. L. Sheild, F.R.C.S.—a daughter.

WADDELL.—On Jan. 3, in Manchester, the wife of Dr. James Waddell—a daughter.

MARRIAGES

HUGHES—CRESSALL.—On Dec. 31, at Alvechurch, Worcs, John Philip Wyndham Hughes, M.D., to Daphne Cressall.

SOLOMONS—EDGAR.—On Nov. 22, in London, Bethel Solomons jun., M.D., M.R.C.P.I., to Gillian Edgar.

DEATHS

BOURDILLON.—On Jan. 4, at Goring-on-Thames, Lancelot Gerard Bourdillon, D.S.O., M.C., M.B. Lond., D.P.H.

BRODY.—On Dec. 30, in Sheffield, Morris Benjamin Brody, M.D. Sheff., D.P.M., aged 37.

CARMICHAEL.—On Jan. 8, in Edinburgh, Archibald Nathaniel Shirley Carmichael, M.B. Edin., F.R.C.P.E., aged 82.

CORSI.—On Jan. 1, in Switzerland, Henry Corsi, M.A., M.B. Camb., F.R.C.S.

EDMOND.—On Jan. 8, William Square Edmond, F.R.C.S.

FARR.—On Jan. 2, at Brighton, Valentine Francis Farr, M.B. Lond., aged 53.

LIVINGSTONE.—On Jan. 3, in London, William Livingstone, M.B. Glasg., aged 88.

MIDDLEWEEK.—On Jan. 3, Frederick Francis Middleweek, L.R.C.P.E., aged 79.

MILNE.—On Jan. 6, James Alexander Milne, M.D., Lond., D.P.H.

NELSON.—On Jan. 6, in London, Wallace Nelson, M.B. Edin.

TUCKETT.—On Jan. 4, at Woodhouse Eaves, Leicestershire, Walter Reginald Tuckett, O.B.E., M.R.C.S., aged 90.

[1] Burn, J. H. Background of Therapeutics. London, 1948; p. 98.

from D2 to D5 as in cardiac denervation—can be performed with ease and safety.

I feel that surgeons who employ this method will be gratified by the increased ease and success of their upper-limb sympathectomies. I hope to publish a more detailed account in the near future.

Dublin. PATRICK FITZGERALD.

SIR,—Following the publication of my letter of Dec. 17, I have been informed that this approach was originally suggested by Mr. W. G. Schulze, of Cape Town, a young surgeon now working in this country. Mr. Schulze did all the preliminary investigation on the cadaver, and eventually introduced the operation to the surgical unit at Cape Town. He informs me that an article will shortly be published, in conjunction with Professor Goetz, which will include a full account of the procedure.

Guy's Hospital. H. J. B. ATKINS
Director, Department of Surgery.

EPILEPSY AND ORGANIC DISEASE

SIR,—Professor Nattrass, in his address to the Manchester Medical Society (*Lancet*, 1949, ii, 994), very rightly emphasised the importance of remembering the existence of organic disease as a possible cause of epilepsy. He quoted the results of post-mortem examinations on 25 cases of patients who had their first fit after the age of 40. In no less than 10 of these the cause of the fits was found to be intracranial tumour.

It should be impressed on all patients who have their first fit after reaching adult life that they should see a neurologist frequently. Epilepsy is a symptom and not a disease *sui generis*. It is high time now to stop confusing ourselves by describing a symptom as an "idiopathic" disease. The word "idiopathic" is defined in the *Shorter Oxford English Dictionary* as "Of the nature of a primary morbid state; not consequent upon another disease." What word could be more defeatist in diagnosis or research? If the cause in any particular case has not been discovered, let it be called "epilepsy of unknown origin."

Dublin. H. W. DALTON.

HEINZ-BODY ANÆMIA AFTER SULPHETRONE

SIR,—Dr. Morlock and Dr. Livingstone, in their article of Dec. 24, mention the known tendency to "hypochromic hæmolytic anæmia, which develops and continues throughout the administration of sulphetrone."

Perhaps it is not generally known that this hæmolytic anæmia is related to the formation of Heinz-Ehrlich bodies in the red corpuscles ("tagged" cells).

Recently a 7-year-old child was given 1 g. of 'Sulphetrone' thrice daily for three and a half days. Two days later (Dec. 19) polychromatic macrocytes and Howell Jolly bodies were present in the blood-film. Further blood-counts showed:

	Dec. 22	*Dec. 23*	*Dec. 28*	*Jan. 3*
Hb, g. per 100 ml. ..	13·5	11·1	9·62	9·99
Red cells, millions per c.mm.	4·2	3·52	2·64	2·86
Colour-index	1·08	1·07	1·2	1·19
"Tagged" red cells, % ..	77·2	67·8	5·4	0
Reticulocytes, % ..	7·4	14·3	23·2	9·6

This hæmolytic anæmia, despite the high reticulocytosis, due to the rapid elimination of the "tagged" cells by the reticulo-endothelial system, was associated with only a slight rise in the blood-bilirubin (0·9 mg. per 100 ml.), and was not accompanied by methæmoglobinæmia. The leaden blue discoloration of the skin was very pronounced. It is unlikely that the administration of iron could counteract the development of this anæmia, which, however, will gradually disappear when the sulphetrone and its split products have been eliminated from the tissues.

By a coincidence your previous issue—that of contained an article, by Dr. Bourne, on the a action of 'Cryogenine.' It is worth mentio similar hæmolytic anæmias occur after cryoge observed in tuberculous patients some years a cryogenine anæmia is due to the formation o hydrazine from the administered phenylsemica

Severe anæmia from these products, both are being used in the treatment of the same —tuberculosis—though with different purposes, averted by withholding the drugs on the appea a high percentage of "tagged" cells.

City General Hospital,
Sheffield, 5.

DEOXYCORTONE ACETATE AND ASCORBIC IN RHEUMATOID ARTHRITIS

SIR,—Like other rheumatologists we were anxi confirm the good results recorded by Lewin and Wa in treating rheumatoid arthritis with deoxyco acetate and ascorbic acid.

Our results agree with those of Kellgren.[3] patients have been treated. All were undoul suffering from rheumatoid arthritis and all sl signs of activity. The treatment was carried out e as described. All were carefully examined befor after the treatment; accurate measurements recorded of the maximum circumference of sw joints (where feasible) and of the range of active m ment. The erythrocyte-sedimentation rate (E.S.R. recorded before and after. No changes in signs observed in any of these cases, and the E.S.R. rema unchanged. One patient said he felt better afte injections and another that he felt dopey; the o felt no change. The one who felt better had a se treatment without any benefit.

INTRAVENOUS INFUSIONS

SIR,—During the past few weeks, some most interesti and helpful notes have been published in your journ concerning the technique of administering intraveno fluids and also the sterilisation of 'Polythene' tubing.

For the past eighteen months, I have been usi polythene tubing (sterilised by boiling) for intraveno therapy, and have found it particularly useful for babie rendering cumbersome splints and difficult immobilisatio of the foot unnecessary, and making nursing muc easier. In adults, I introduce it into a forearm vei through a needle, or by cutting down on a vein an tying it off in the usual way. So far, I believe, m results are better than those obtained by the olde methods. The method allows the patient freedom o movement, and I can usually keep the same vein in use for five or six days. The end-result, however, is always the same; thrombophlebitis develops, necessitating the removal of the tubing.

I have been trying to perfect this technique for the continuous administration of penicillin in cases of subacute bacterial endocarditis. In my last patient, I introduced the tubing through a needle into a forearm vein with strict aseptic technique. The patient was

Tonkinson, W. C. Turner, J. M. Urquhart, P. A. M. van de Linde, P. H. Vernon, J. L. Walsh, F. L. Wheaton, W. A. Young.

Mr. E. H. F. Baldwin, PH.D., has been appointed to the chair of biochemistry at University College.

On Monday, Jan. 23, at 5.30 P.M., at the London School of Hygiene, Keppel Street, W.C 1, Prof. P. Grabar, of the Pasteur Institute, Paris, will give a lecture on Origins and Functions of Globulins and Antibodies. On Tuesday, Feb. 7, at 5 P.M. at Westminster Medical School, Dr. J. G. Borst, professor of internal medicine in the University of Amsterdam, is to give a lecture on the Circulation in Disease.

The following courses have also been arranged: Mr. F. Bergel, D.SC., four lectures on Pharmacological Chemistry (beginning on Friday, Jan. 20, at 5.15 P.M.); Dr. L. C. Thomson, three lectures on Visual Physiology (beginning on Tuesday, Feb. 7, at 5.15 P.M.); Dr. Tudor Jones, three lectures on the Peptide Bond in Biochemistry (beginning on Thursday, Feb. 23, at 4.45 P.M.). All the lectures will be held at University College, Gower Street, W.C.1.

Order of St. John of Jerusalem

The King has sanctioned the following promotions in, and appointments to, this order:

As Knight.— Colonel J. L. Hamilton, M.C., M.D.

As Commanders.—H. E. Skeete, O.B.E., M.D.; F. R. B. H. Kennedy, M.B.E., L.R.C.P.E.; James Lamberton, M.B.; E. H. Shaw, M.D.; O. T. J. C. de H. Clayre, M.R.C.S.; F. H. Edwards, F.R.C.S.E.; Lieut.-Colonel William George, M.C., M.B.; W. F. J. Whitley, M.D; Hon. Paul Boffa, O.B.E., M.D.; Arthur Percy Spark, M.B.

As Associate Commander.—Gopal Haridas, M.R.C.P.

As Officers.—C. P. Craggs, M.B.; Paul Grima, M.D.; F. L. Firkin, M.B.; Major A. R. Home, M.B.; B. S. Collings, M.R.C.S.; R. H. O. Garbutt, L.R.C.P.E.; A. J. Owston, M.R.C.S.; E. H. Capel, M.D.; Brigadier A. L. Dawkins, O.B.E., F.R.C.S.

As Associate Officer.—B. C. Cohen, M.B.

Appointments to Boards of Teaching Hospitals

The Minister of Health has made the following appointments to the boards of governors of London teaching hospitals:

University College Hospital.—Dr. J. C. Hawksley, F.R.C.P.

Hospital for Sick Children.—Dr. G. H. Newns.

Hospital for Diseases of the Chest.—Dr. A. Hope Gosse, F.R.C.P.

Congress on Gastroenterology

The second European congress of the National Association of Gastroenterology will be held in Madrid from May 4 to 7, when there will be discussions on all diseases of the biliary tract except lithiasis and cancer. The speakers will include Prof. R. A. Gregory and Dr. A. H. Douthwaite. Further information may be had from the general secretary, Jorge Juan 41, Madrid.

Congress on Diseases of the Chest

The first International Congress on Diseases of the Chest will be held at the Carlo Forlanini Institute, Rome, from Sept. 17 to 20, under the auspices of the council on international affairs of the American College of Chest Physicians and the Carlo Forlanini Institute. Further information may be had from Prof. A. Omodei Zorini, Carlo Forlanini Institute, Rome, Italy, or from Dr. Chevalier L. Jackson, 500, North Dearborn Street, Chicago 10, Illinois, U.S.A.

Midland Institute of Otology

This institute, which was founded in 1947, held its annual general meeting in Birmingham on Oct. 27. The following were elected as officers for the ensuing year: president, Mr. W. Stirk Adams; vice-president, Mr. W. L. Thomas; honorary secretary, Mr. Reginald S. Strang; honorary treasurer, Mr. W. H. Lomas; members of council, Mr. B. S. Carter, Mr. J. B. Cavenagh, Mr. E. Collins, Mr. Robert Evans, Mr. F. Brayshaw Gilhespey, Mr. Hamilton Baynes, and Mr. Sydney Vernon.

Fellowship for Freedom in Medicine

The membership of this fellowship now exceeds 3000.

R.A.F. Appointment

Air Commodore W. E. Barnes has been appointed principal medical officer of Technical Training Command with the acting rank of air vice-marshal.

British Association of Plastic Surgeons

The following officers have been elected for 1950: president, Mr. Rainsford Mowlem; hon. treasurer, Mr. R. P. Osborne; hon. secretary, Mr. J. P. Reidy; editor of journal, Mr. A. B. Wallace; council, Mr. J. N. Barron, Mr. R. J. V. Battle, Sir Harold Gillies, Mr. W. Hynes, Prof. T. Pomfret Kilner, Sir Archibald McIndoe, Mr. J. S. Tough.

King Edward's Hospital Fund for London

The Fund has received a further instalment of £100,000 from the Nuffield Trust for the Special Areas. Lord Nuffield provided that any sums which might later be available from this trust should pass to the King's Fund. A total of £1¼ million has now been received.

Incidence of Sickness Claims

In England and Wales new claims to sickness benefit under the National Insurance Act during the weeks ended Dec. 6, 13, 20, and 27, 1949, numbered 119,100, 109,300, 99,700, and 58,900. The weekly averages in the months from January to November, 1949, were as follows: 157,900, 179,800, 185,200, 114,400, 97,700, 83,500, 78,600, 88,800, 100,900, 119,100, and 136,200. These figures are given in the Registrar-General's return of births and deaths for the week ended Dec. 31.

Teaching-hospital Secretaries

The Industrial Court has awarded secretaries of undergraduate teaching hospitals a salary of £1750 on appointment, rising by steps to £2000 after four years; the scale is to apply from July 5, 1949. The Minister of Health, in a letter to boards of governors, has expressed the view that each of these secretaries "should normally have direct administrative responsibility for one or more of the hospitals in the teaching group, as well as acting as Secretary to the Board and chief administrative officer of the hospital group."

Salaries of Hospital Pharmacists

The following scales for hospital pharmacists have been agreed following an award by the Industrial Court:

	£
Pharmacist	425–25–525
Senior pharmacist	475–25–575
Deputy chief pharmacist	525–25–625
Chief pharmacist:	
Category I	525–25–625
Category II	575–25–675
Category III	625–25–725
Category IV	675–25–825

Employment of the Tuberculous at Sanatoria

In a memorandum to hospital authorities the Ministry of Health suggests that "the practice of employing tuberculous persons on the staffs of sanatoria is a valuable contribution to the provision of suitable employment for those whose condition restricts the scope of work which they can undertake without detriment to their own health or risk to others." The advantages of this practice, says the memorandum, "are that restored tuberculosis patients are enabled to earn a livelihood in a familiar environment under constant medical supervision and to have the amount and nature of their work adjusted to individual needs and capabilities; that the tuberculosis hospital service is helped by using men and women with personal experience of the disease; and that in such persons, especially when acting as nurses, patients under treatment find a particular degree of sympathy and understanding." There are, however, difficulties. The health of these tuberculous people "may be precarious and prevent them doing as much as a completely fit person. There is also the possibility that their employment may give rise to a fear of infection among others working with them who are not tuberculous. At large institutions experience has shown that this difficulty may be largely met by arranging separate living accommodation; and at smaller institutions an expedient might be to arrange for the healthy staff to be mainly non-resident."

Notes and News

ANOTHER CASE OF POISONING

THE Ministry of Health, with the collaboration of the Central Council for Health Education and with the advice of Prof. Robert Cruickshank, have sponsored a new Central Office of Information film on the need for cleanliness in handling food. *Another Case of Poisoning*, a 15-minute sound film, is built around a patient to whom everything seems to happen (including having his abdomen palpated through his pyjama jacket), and draws attention to the sources of food contamination in home, factory, and shop. First the danger of not washing the hands after using the lavatory is emphatically stressed, and then all the other faults—the housewife who is not particular about her cleanliness in preparing meals; a butcher who fondles animals and handles meat with his hand in a dirty bandage, and who keeps meat pies in the window with flies crawling over them; the café with the cutlery standing in dirty water, and unclean waitresses and kitchen staff; the barmaid who wipes the counter and then the glasses with the same cloth; the girl in the food factory who sneezes over the cream buns that she is preparing; the man handling trays of food and letting the ash from his cigarette drop over them.

The film has been available, without charge, from Jan. 1, and the Ministry hope that medical officers of health, catering firms, and other institutions employing food-handlers will arrange to show it. They consider its value will be greatly increased if it is included in a lecture, or preceded by a background talk given by someone who could deal with questions from the audience. Although the film has been made primarily for food-handlers, it is hoped that showings for housewives will also be arranged. Borrowers who have a 16 mm. sound projector should apply to the Central Film Library, S.W.7; others to the films division of the Central Office of Information, 83, Baker Street, W.1. An earlier film, *The Good Housewife in the Kitchen*, which deals with hygienic storage of food in the larder and kitchen, is also available.

The Ministry of Health have also sponsored three trailers: *Handkerchief Drill*, *Scalding Hot* (hints on prevention of such accidents in the home), and *Nothing in the Bottle* (a plea for a return of the 2 million medicine bottles issued each week under the National Health Service).

ROYAL MEDICAL BENEVOLENT FUND

THE Christmas Gift appeal made by Lord Webb-Johnson, president of the R.M.B.F., brought in £2591 7*s.* 7*d.*—a better response than ever before. The committee decided that in present circumstances the gifts ought to be larger than the usual £5, and they authorised a distribution of £10 to each beneficiary. This cost £4590, made up as follows:

	£	s.	d.
Donations to the Christmas Appeal ..	£2591	7	7
From the general funds	£1998	12	5
	£4590	0	0

The gratitude expressed by all the recipients proved how greatly this work of extra benevolence during the winter months is appreciated and valued.

CORTISONE FROM A BOTANICAL SOURCE

LAST summer there seemed to be good hope that 'Cortisone' might be produced in increased quantities and at smaller cost from sarmentogenin, which is derived from the seeds of *Strophanthus sarmentosus*.[1] This vine is to be found in Liberia, but a recent report [2] indicates that here there exists no large ready source of the substance. The seed ripens in an elongated pod 11–12 months after the vine has flowered and fruited; but a research-worker living in Liberia has observed that a liane which grew beside his house, though it flowered profusely each year, fruited only twice in eight years. Africans use the seed pods to make hunting arrows and for medicinal purposes, and the best chance of successful collection is in uninhabited areas. Colonel Hildrus A. Poindexter, director of the United States Public Health Service mission in Liberia, has estimated that at least twenty years will be required to solve the botanical problems in its commercial growth as a source of cortisone.

A Medical Research Council expedition left for Nigeria last November.

RESEARCH INTO DEAFNESS

THE trustees of the Alexander Pigot Wernher memori trust, through the Medical Research Council, have establish a research unit on deafness at the Institute of Laryngolo and Otology (University of London). Mr. T. S. Littler, PH.D., has been appointed director of the unit, and Miss E. Whetnal F.R.C.S. assistant director. The unit has also the assistan of Mr. D. B. Fry, consultant in phonetics to the institute, and of a staff of research registrars, physicists, and technician The unit is housed at the Golden Square Hospital, where it will work in close association with the deafness aid clinic of the Royal National Throat, Nose, and Ear Hospital. Its programme includes investigation of improved treatment of otitis media and of deafness developing with age; methods of measuring residual hearing for adults and children, and the various problems associated with the use and design of hearing-aids are also being studied. The unit has agreed to carry out research on behalf of the electro-acoustics committee of the Medical Research Council and the Ministry of Health.

AMENDMENTS TO THE NATIONAL FORMULARY 1949

THE Joint Formulary Committee has decided that, where preparations appear in the *National Formulary 1949* and the *British Pharmaceutical Codex 1949* under the same main title or synonym, they shall, with the exception of guttæ cocainæ and tabellæ ferri sulphatis compositæ, be dispensed or prepared according to the formula of the 1949 *Codex* from the date on which the Minister of Health decides that this shall replace the 1934 *Codex* for National Health Servic purposes. The following list gives those preparations of the *National Formulary* which are chiefly affected by this decisio (where the main titles are not identical, that of the corre sponding *B.P.C.* preparation is given in parentheses):

Applicatio dicophani.

Collodium acidi salicylici.

Collyrium: acidi borici, acidi citrici, boracis compositum hydrargyri oxycyanidi, sodii bicarbonatis, sodii chloridi, zinc compositum.

Conspersus: acidi salicylici compositus, hydrargyri subchlorid compositus, talci boricus (talci borici *B.P.C.*), zinci oxidi et amyl compositus.

i oxid

.P.C.

B..

mitis

sulphati-

inæ, lachesinæ, penicillini, physo-

, zinci sulphatis.

Insufflatio argenti picratis.

Liquor: boracis et formaldehydi, iodi simplex.

Lotio: calaminæ oleosa, cupro-zincica (cupri et zinci sulphatum *B.P.C.*), picis carbonis et plumbi, plumbi, plumbi et glycerini plumbi evaporans.

Mistura: ammoniæ ... ammonii chlorid et morphinæ, cascaræ ... tis, ipecacuanhæ alkalina, potassii bromi ... aleriane, potassii iodidi ammoniata, rhei

Pasta: picis carbonis, ... composita *B.P.C.*), resorcinolis mitis (resorcinolis composita mitis *B.P.C.*), zinci oxidi cum acido salicylico.

Pigmentum: iodi compositum, iodoformi compositum, podophylli, tinctorium.

Tabellæ ferri carbonatis.

Trochisci: ammonii chloridi, formaldehydi.

Unguentum: acidi benzoici compositu acidi salicylici et sulphuris, cinchocainæ forte, hydrargyri ammoniati et picis carb denigrescens, iodi denigrescens cum methylis salicylate.

Mistura pro infantibus: acidi acetylsalicylici, ipecacuanh ammoniata, stramonii et potassii iodidi.

University of Oxford

In a congregation held on Dec. 15, the following degrees were conferred:

D.M.—R. G. Harrison, C. W. M. Whitty.

B.M.—J. C. S. Ainley-Walker, M. de G. Gribble, Anthony Ryle, John Hamill, A. S. Welbourne, I. K. Anderson, J. H. Wakely, D. D. Stephens, M. T. Ashcroft, D. E. Freeland, R. W. Gilliatt, A. D. Munro-Faure, G. M. Robertson, J. F. T. Allison, Murray Brookes, H. I. Jory, A. M. O. Blood, W. H. J. Summerskill,* J. E. von Bergen, Lawrence Mackie, Arnold Cohen, H. V. James, M. C. Spencer, Sheila von Bergen, Elizabeth F. Browne, Honor E. Bambridge, Faye V. Tallack, Patricia J. A. Cooper, Joan Wheelwright, Edith M. W. Elliott.

* In absentia.

Royal College of Physicians of London

Sir Weldon Dalrymple-Champneys will deliver the Milroy lectures at the college, Pall Mall East, S.W.1, on Tuesday and Thursday, Feb. 14 and 16, at 5 P.M. He has chosen as his subject Undulant Fever, a Neglected Problem.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

REPORT OF FIVE CASES

M. R. EWING
M.B. Edin., F.R.C.S., F.R.C.S.E.
SENIOR LECTURER IN SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

WITHIN the past year I have encountered a succession of postoperative palsies of the upper extremity, two of which have been widespread and severely incapacitating. Though fortunately every case has almost completely recovered, the distress caused to the patient by this avoidable disability has been considerable, to say nothing of the disturbance to the surgeon's peace of mind.

The risk of these paralyses has been widely known since the turn of the century, but it is my impression, both from discreet inquiry and from the frank admissions of surgeons and anæsthetists elsewhere, that they have been increasingly frequent in recent years. Perhaps this paper may encourage others to report similar experiences.

CASE-RECORDS

Case 1.—A relatively fit man, aged 37, weighing 11 st. 6 lb., had a carcinoma of the rectum. On Oct. 11, 1948, the rectum was resected by the synchronous combined abdominoperineal technique, Lloyd-Davies leg supports being used. Anæsthesia was induced with thiopentone and endotracheal ether, and supplemented with repeated small doses of curare. The operation took about two hours, and for part of this time there was a slight head-down tilt of the table. Bleeding was considerable, and the patient was transfused generously during the operation. A vein on the volar aspect of the left forearm was used for venoclysis, and infusion was continued into this arm for some days after operation. It is almost certain that, while the patient was on the table, this arm was maintained in abduction, extension, and lateral rotation at the shoulder.

The patient's general condition after operation was not good, and it was nearly a week later, when he was somewhat better, that he complained of discomfort in the left upper arm. This was attributed at the time to phlebitis in a superficial vein following a protracted spell of infusion. Almost two months later (on Dec. 2) at a follow-up examination the patient complained of persisting weakness of the left arm, and was found to have a wasted and paralysed biceps. By Feb. 24, 1949, there was still no voluntary contraction of the left biceps and no response to faradism, but when last seen on Aug. 12, the patient had no disability and the wasting was less evident.

Case 2.—A man, aged 42, had a rectal carcinoma complicated by unremitting and urgent bleeding. On Sept. 30, 1948, after generous transfusions, what was virtually an emergency abdominoperineal resection was done. He had a long-standing deeply ulcerating growth and was a poor subject for operation. He gave a history of repeated fractures in early life, was of very short stature, and weighed only 7 st. 6 lb. X-ray examination suggested that he had healed polyostotic fibrous dysplasia. The operation was done by the synchronous combined abdominoperineal method, Lloyd-Davies leg supports, shoulder rests, and a slight Trendelenburg tilt being used. The arms were secured in the "crucifix" position to a simple long arm-board passed under the sponge-rubber table-cover at shoulder level. A drip transfusion was given into a vein in one forearm (we have no record of which side was used), and the sphygmomanometer cuff was applied to the other. As was our custom, the wrists were padded with gamgee and secured with a webbing belt, a folded sheet of cotton-wool being placed behind the extended elbow, and the forearm fixed in supination. The shoulder on each side was abducted to 90°.

General anæsthesia was induced with thiopentone, gas, oxygen, and ether by the endotracheal route, and this was supplemented throughout the operation with small repeated doses of curare. The operation, which involved resection of a portion of the bladder and prostate, took almost three hours.

The patient was very ill for some days subsequently, and almost every accessible vein in each arm was used at one time or another for infusion. When in the first week after operation he complained of discomfort in the muscles of the upper arm, it was, as in case 1, first attributed to thrombosis in these much abused superficial veins.

Later the patient developed an intractable urinary fistula and remained in hospital for many months, but it was not until Feb. 8, 1949, when he called my attention to his thin upper arm, that I discovered that his biceps on the left side was both weak and wasted. Elbow flexion and supination were severely impaired, the voluntary muscle power in the biceps being recorded on Feb. 28 as 2 (M.R.C. coding). There was no response to faradism. The patient also complained of some numbness on the dorsum of the thumb and along the radial border of the forearm, but no sensory dysfunction could be demonstrated. On being questioned at this stage he said (and he was most reliable and observant) that weakness had also appeared immediately after operation in the right arm, making shaving almost impossible. He had had at this time several accidents when lifting cups of tea or a water-jug from his bedside table. He had noted steady progressive recovery in the succeeding weeks, and there was no obvious impairment of motor power in this arm when I examined it on Feb. 8. The history, however, left me in no doubt that his musculocutaneous nerve had also been damaged on the right side, but had completely and spontaneously recovered. When the patient left hospital on June 15 recovery on the left side was still imperfect.

Case 3.—A thin and rather frail woman, aged 67, underwent an operation for exploration of the common bile-duct on April 20, 1948. The anæsthetic was induced with ether, supplemented with curare, and the operation took rather less than $1\frac{1}{2}$ hours. The arms were secured to a double arm-board in the "crucifix" position, and the costal margin was pushed forward by the insertion of two opposed wooden wedges under the thoracolumbar region. A continuous intravenous drip was set up in the left forearm and was maintained for the next 24 hours.

On the day after operation the patient complained of weakness of the right hand and forearm, and could not extend the elbow to reach objects on her bedside table. The triceps (all three heads), the dorsiflexors of the wrist, and the extensors of the metacarpophalangeal joints were mainly affected, but there was also some weakness of the abductors of the 4th and 5th fingers and hyperæsthesia in the ulnar distribution. By the third postoperative day the patient could carry out all movements against gravity except extension at the metacarpophalangeal joints, and there was no sensory impairment. When last seen, in September, 1948, her recovery had long since been complete and there was no residual disability.

Case 4.—A short stout woman, aged 59, weighing 9 st. 2 lb., was operated on for resection of a carcinoma of the pelvic colon involving the bladder, on Jan. 10, 1949. Anæsthesia was induced with thiopentone and maintained with endotracheal gas and oxygen, supplemented with curare. The operation lasted for about $2\frac{1}{2}$ hours, for most of which time the patient was in a mild Trendelenburg tilt, with shoulder-rests in position. Both arms were abducted and extended at the shoulder and were secured in the "crucifix" position to a double arm-board, the right being used for blood-transfusion and the left for a sphygmomanometer cuff.

On recovering from the anæsthetic the patient complained of weakness of the right arm. There was complete loss of abduction at the shoulder, though the suprascapular and long thoracic nerves were unaffected. There was some feeble contraction of the triceps but none was perceptible in the biceps. The muscles supplied by the median and ulnar nerves were intact, but there was loss of supination of the forearm and of dorsiflexion at the wrist. There was no sensory loss.

From the beginning there was slow but steady improvement, and, when the patient was discharged home, on Feb. 2, the wrist-drop had virtually disappeared. The weakness of the biceps (especially) and of the other supinators was, however, still obvious.

Case 5.—A fit and well-nourished woman, aged 54, weighing 12 st. 1 lb., had a carcinoma high in the rectum; this was resected from the abdomen, with preservation of the sphincters, on March 14, 1949. Anæsthesia was induced with thiopentone and maintained with endotracheal cyclopropane,

Conference on Maternity and Child Welfare

The National Association for Maternity and Child Welfare will hold their annual conference on June 28, 29, and 30, at Friends House, Euston Road, London, N.W.1. Further information may be had from the secretary of the association, 5, Tavistock Place, W.C.1.

British Health Resorts Association

A meeting of the old council and members of this association will be held on Wednesday, Jan. 18, at 4.30 P.M., at 11, Chandos Street, London, W.1, to elect a new council and officers so that the association may be revived. Others who are interested are invited to attend. The acting hon. secretary is Dr. M. B. Ray.

British Standards of Hospital Equipment

Hospital authorities have been urged by the Ministry of Health to "use the published British Standards to the maximum practicable extent in purchasing equipment and supplies. Wherever possible, it should be a condition of contracts and orders that the quality of the goods to be supplied shall not be inferior to that specified in the appropriate British Standard and they shall be made to the standard dimensions laid down. This is the practice where purchases are made centrally."

Laboratory Animals

The Laboratory Animals Bureau is holding a congress of animal attendants on Thursday and Friday, March 30 and 31, at the Royal Veterinary College, Royal College Street, London, N.W.1. The congress is open to those, other than university graduates, whose work involves the use, care, and handling of laboratory animals; it is not restricted to senior animal attendants. Applications for tickets should be sent to the director of the bureau, at the college.

Sickness Benefit

According to the Ministry of National Insurance, some self-employed people are under the impression that they cannot draw sickness benefit during the first four weeks of illness. The self-employed are in fact in the same position as the employed: normally they can get sickness benefit after the third day of illness, and in some circumstances from the first day. Both self-employed and employed should send a medical certificate to the local National Insurance office within three days of the first day of incapacity; or, failing this, the office should be notified by letter, and the medical certificate should follow as soon as possible and certainly within ten days from the first day of incapacity.

Proposed Health Advisory Council for Manchester Region

Discussions have lately taken place between representatives of the Manchester regional hospital board, the board of governors of the United Manchester Hospitals, and some executive councils and local health authorities in the region to consider the best way of helping the different authorities providing health services in the region to work together. At a meeting held on Oct. 31 it was decided that an advisory council should be set up to discuss matters affecting the joint interests of two or more of the constituent bodies; to advise on the coördination of health services; and to disseminate information to the constituent bodies. The council will consist of 8 representatives of hospital interests (6 appointed by the regional hospital board, and 2 by the board of governors of the United Manchester Hospitals); 8 representatives appointed by the local health authorities; and 8 appointed by the executive councils.

Ministry of Food Bulletin.—This weekly bulletin is now available to the public through H.M. Stationery Office. It has been published for ten years but its circulation has been limited to the staff of the Ministry and other Government departments. The annual subscription is £1 1*s*. including postage, and single copies will be sold at 4*d*., postage 1*d*.

The Society of Chemical Industry is starting publication of a new monthly, the *Journal of the Science of Food and Agriculture*, which will contain original articles and reviews of recent work. It is obtainable by non-members at 30*s*. per annum, or 3*s*. for a single copy, on application to the society, 56, Victoria Street, London, S.W.1.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

REPORT OF FIVE CASES

M. R. EWING
M.B. Edin., F.R.C.S., F.R.C.S.E.
SENIOR LECTURER IN SURGERY, POSTGRADUATE MEDICAL SCHOOL OF LONDON

WITHIN the past year I have encountered a succession of postoperative palsies of the upper extremity, two of which have been widespread and severely incapacitating. Though fortunately every case has almost completely recovered, the distress caused to the patient by this avoidable disability has been considerable, to say nothing of the disturbance to the surgeon's peace of mind.

The risk of these paralyses has been widely known since the turn of the century, but it is my impression, both from discreet inquiry and from the frank admissions of surgeons and anæsthetists elsewhere, that they have been increasingly frequent in recent years. Perhaps this paper may encourage others to report similar experiences.

CASE-RECORDS

Case 1.—A relatively fit man, aged 37, weighing 11 st. 6 lb., had a carcinoma of the rectum. On Oct. 11, 1948, the rectum was resected by the synchronous combined abdominoperineal technique, Lloyd-Davies leg supports being used. Anæsthesia was induced with thiopentone and endotracheal ether, and supplemented with repeated small doses of curare. The operation took about two hours, and for part of this time there was a slight head-down tilt of the table. Bleeding was considerable, and the patient was transfused generously during the operation. A vein on the volar aspect of the left forearm was used for venoclysis, and infusion was continued into this arm for some days after operation. It is almost certain that, while the patient was on the table, this arm was maintained in abduction, extension, and lateral rotation at the shoulder.

The patient's general condition after operation was not good, and it was nearly a week later, when he was somewhat better, that he complained of discomfort in the left upper arm. This was attributed at the time to phlebitis in a superficial vein following a protracted spell of infusion. Almost two months later (on Dec. 2) at a follow-up examination the patient complained of persisting weakness of the left arm, and was found to have a wasted and paralysed biceps. By Feb. 24, 1949, there was still no voluntary contraction of the left biceps and no response to faradism, but when last seen on Aug. 12, the patient had no disability and the wasting was less evident.

Case 2.—A man, aged 42, had a rectal carcinoma complicated by unremitting and urgent bleeding. On Sept. 30, 1948, after generous transfusions, what was virtually an emergency abdominoperineal resection was done. He had a long-standing deeply ulcerating growth and was a poor subject for operation. He gave a history of repeated fractures in early life, was of very short stature, and weighed only 7 st. 6 lb. X-ray examination suggested that he had healed polyostotic fibrous dysplasia. The operation was done by the synchronous combined abdominoperineal method, Lloyd-Davies leg supports, shoulder rests, and a slight Trendelenburg tilt being used. The arms were secured in the "crucifix" position to a simple long arm-board passed under the sponge-rubber table-cover at shoulder level. A drip transfusion was given into a vein in one forearm (we have no record of which side was used), and the sphygmomanometer cuff was applied to the other. As was our custom, the wrists were padded with gamgee and secured with a webbing belt, a folded sheet of cotton-wool being placed behind the extended elbow, and the forearm fixed in supination. The shoulder on each side was abducted to 90°.

General anæsthesia was induced with thiopentone, gas, oxygen, and ether by the endotracheal route, and this was supplemented throughout the operation with small repeated doses of curare. The operation, which involved resection of a portion of the bladder and prostate, took almost three hours.

The patient was very ill for some days subsequently, and almost every accessible vein in each arm was used at one time or another for infusion. When in the first week after operation he complained of discomfort in the muscles of the upper arm, it was, as in case 1, first attributed to thrombosis in these much abused superficial veins.

Later the patient developed an intractable urinary fistula and remained in hospital for many months, but it was not until Feb. 8, 1949, when he called my attention to his thin upper arm, that I discovered that his biceps on the left side was both weak and wasted. Elbow flexion and supination were severely impaired, the voluntary muscle power in the biceps being recorded on Feb. 28 as 2 (M.R.C. coding). There was no response to faradism. The patient also complained of some numbness on the dorsum of the thumb and along the radial border of the forearm, but no sensory dysfunction could be demonstrated. On being questioned at this stage he said (and he was most reliable and observant) that weakness had also appeared immediately after operation in the right arm, making shaving almost impossible. He had had at this time several accidents when lifting cups of tea or a water-jug from his bedside table. He had noted steady progressive recovery in the succeeding weeks, and there was no obvious impairment of motor power in this arm when I examined it on Feb. 8. The history, however, left me in no doubt that his musculocutaneous nerve had also been damaged on the right side, but had completely and spontaneously recovered. When the patient left hospital on June 15 recovery on the left side was still imperfect.

Case 3.—A thin and rather frail woman, aged 67, underwent an operation for exploration of the common bile-duct on April 20, 1948. The anæsthetic was induced with ether, supplemented with curare, and the operation took rather less than $1^1/_2$ hours. The arms were secured to a double arm-board in the "crucifix" position, and the costal margin was pushed forward by the insertion of two opposed wooden wedges under the thoracolumbar region. A continuous intravenous drip was set up in the left forearm and was maintained for the next 24 hours.

On the day after operation the patient complained of weakness of the right hand and forearm, and could not extend the elbow to reach objects on her bedside table. The triceps (all three heads), the dorsiflexors of the wrist, and the extensors of the metacarpophalangeal joints were mainly affected, but there was also some weakness of the abductors of the 4th and 5th fingers and hyperæsthesia in the ulnar distribution. By the third postoperative day the patient could carry out all movements against gravity except extension at the metacarpophalangeal joints, and there was no sensory impairment. When last seen, in September, 1948, her recovery had long since been complete and there was no residual disability.

Case 4.—A short stout woman, aged 59, weighing 9 st. 2 lb., was operated on for resection of a carcinoma of the pelvic colon involving the bladder, on Jan. 10, 1949. Anæsthesia was induced with thiopentone and maintained with endotracheal gas and oxygen, supplemented with curare. The operation lasted for about $2^1/_2$ hours, for most of which time the patient was in a mild Trendelenburg tilt, with shoulder-rests in position. Both arms were abducted and extended at the shoulder and were secured in the "crucifix" position to a double arm-board, the right being used for blood-transfusion and the left for a sphygmomanometer cuff.

On recovering from the anæsthetic the patient complained of weakness of the right arm. There was complete loss of abduction at the shoulder, though the suprascapular and long thoracic nerves were unaffected. There was some feeble contraction of the triceps but none was perceptible in the biceps. The muscles supplied by the median and ulnar nerves were intact, but there was loss of supination of the forearm and of dorsiflexion at the wrist. There was no sensory loss.

From the beginning there was slow but steady improvement, and, when the patient was discharged home, on Feb. 2, the wrist-drop had virtually disappeared. The weakness of the biceps (especially) and of the other supinators was, however, still obvious.

Case 5.—A fit and well-nourished woman, aged 54, weighing 12 st. 1 lb., had a carcinoma high in the rectum; this was resected from the abdomen, with preservation of the sphincters, on March 14, 1949. Anæsthesia was induced with thiopentone and maintained with endotracheal cyclopropane, supplemented with curare. The operation lasted $3^{1}/_{2}$ hours, and for most of this period the patient was in a slight head-down position, with the legs flexed at the knee and secured to the dropped end of the table, and the shoulders supported by padded rests. The left arm was used for blood-transfusion, being secured for this purpose in abduction, with the elbow extended and the forearm supinated.

On the morning after operation the patient had an almost complete paralysis of both upper extremities. On the right side she could feebly flex the fingers and adduct the thumb. The triceps too was contracting but could not extend the elbow against gravity. On the left side movement was limited to poor flexion of fingers 1–4 and to adduction of the thumb. There was also diminished sensation to pinprick on the radial border of each forearm. The patient was severely incapacitated, being totally unable to move in bed, feed herself, turn the pages of a book, or even hold a newspaper.

Recovery was steady from the start, beginning with the return of power in the long flexors and in the extensors of the elbow and wrist. Shoulder movements, including abduction, soon followed, and the last movements to return were elbow flexion and supination. The left arm lagged behind the right at all stages in the recovery. None of the muscle groups in either arm lost at any stage their response to faradism, but on April 28, voluntary power of the left biceps was still recorded as 1, and of the left supinator as 0. The patient at this stage could do all things for herself, including combing her hair and dressing her temporary colostomy. By June 2 there was almost complete recovery in the right arm. The left arm was, however, still weak especially the movements of elbow flexion and of supination of the forearm. The grip on this side was also deficient, especially flexion of the thumb and of the index and middle fingers. The patient reported that until recently these fingers had felt rather clumsy and useless, and sensation had been apparently dulled, but this was now returning.

DISCUSSION

Mechanism

The most comprehensive paper on postoperative nerve palsies that I have been able to trace among those written in recent years is that of Clausen (1942). He reported 9 such cases affecting the brachial plexus and put forward suggestions concerning the mechanism of this injury. Though he mentioned that in certain positions of the arm the plexus may be compressed between the clavicle and the first rib, he was not impressed with this as an important cause of damage, and with this view I heartily agree. It is well known that this complication is especially frequent after operations in which a Trendelenburg tilt has been used. This was certainly true in 4 out of 5 of my patients, in 6 out of the 9 Clausen reported, in all 3 of Baldwin's (1928), and in 3 of the 4 in Achard's (1946) series.

It is widely believed that the damage is caused in this position by the direct pressure of an inadequately padded and incorrectly placed shoulder-rest, which is presumed to bear directly on the plexus before it leaves the root of the neck to pass behind the clavicle. Care is accordingly taken, not only to make certain that the brace is generously covered with 'Sorbo' rubber and cotton-wool but also that it comes to lie opposite the acromion and not further medially, where it can press on the soft tissues over the posterior triangle. Baldwin was of the opinion that the rests were responsible in all of his cases, and was satisfied that the latter use of a carefully padded broad shoulder-yoke, which he described, had been responsible for the elimination of this complication from his gynæcological clinic.

I do not deny for a moment that it is wise to take such precautions, but in my view tension or stretching is much more important than direct compression. The plexus is deeply placed in the root of the neck, buffered by tough fascial layers, and sheltered from above and behind by the fairly generous muscle belly of trapezius. It is therefore difficult to bring pressure to bear directly on the plexus; or so at least it seems when one attempts this manœuvre in the cadaver. I find it hard to believe that an unpadded shoulder-rest, even of the not uncommon semicircular pattern, can press directly on the major nerve-trunks in the root of the neck. Moreover, as Denny-Brown and Brenner (1944) have made clear, the primary cause of the disturbance of nerve function which follows pressure on a nerve is obliteration of its vessels, with resulting ischæmia. It was, however, in their experience exceedingly difficult to cause any such disturbance in a major nerve-trunk: "its compartmented physical structure . . . is such as to protect some of the longitudinal vessels from exposed pressure." They found in fact that, even with direct pressure exerted on a bare nerve by a mercury bag, small blood-vessels could remain patent in the interstices between blanched nerve bundles. That direct pressure from the shoulder brace is not an important cause is also suggested by the occurrence of paralysis when the arms have been secured by the wrists, and when incorrectly placed shoulder-rests have not taken any of the body-weight in the Trendelenburg position (as was the case with one patient in Clausen's series).

Quite the most vulnerable position in our view is that of a Trendelenburg tilt combined with abduction at the shoulder. In many operations these days an arm vein is wanted for the giving of thiopentone or other drugs, or for the infusion of blood or saline, and often for this purpose the arm is brought out from the side and secured to an arm-board. This was certainly true in all 5 of my cases, and 4 of the 6 patients in Clausen's series had a venoclysis at operation in what was subsequently the paralysed limb. Every one of Baldwin's patients, too, was given, during the operation, a saline infusion. We are told that these operations were done with the patients' arms folded across the chest. It seems not unlikely, however, that the infusions were given into arm veins, and no doubt the limbs were, for a time at least, brought out into abduction. However, Baldwin was prepared to discount the rôle of the position of the arm during infusion, largely on the ground that it was a routine in all major pelvic operations, most of which, of course, escaped paralysis. In every one of the 4 cases reported by Achard (1946) the affected arm had been brought out into abduction during the operation, in 3 instances for blood-transfusion.

Denny-Brown and Doherty (1945) have shown that a nerve can be damaged by stretching. This is probably especially true of the major nerve-trunks, which are not so extensible as their more peripheral and smaller divisions. (Experimentally, however, these workers found it difficult to injure the bigger nerves by stretching.)

The nerve-trunks of the upper extremity are anchored at their points of emergence from the vertebral column and probably, too, at their ultimate points of distribution, or alternatively, as Clausen suggests, by their fascial attachments in the axilla. Though nerves are extensible, there is a limit to the amount of stretching they can withstand, and any position which involves, for long enough, too wide a separation of the fixed ends of the nerve is likely to be injurious. With the arm by the side, the separation of the two ends is at its maximum when the fingers and wrist are dorsiflexed, the elbow extended, and the forearm in full supination. Extension of the neck and pulling of the head over towards the opposite side may add a little more.

Now the nerve bundles pass distally along the medial aspect of the arm, so any limb movement in front of the coronal plane of the trunk and below the level of the shoulder is unlikely to cause any harm, excepting always some gross avulsing injury involving distraction at the shoulder-joint. When, however, the arm is pulled up into abduction at the shoulder, in the coronal plane of the trunk or behind it, there are several anatomical structures round which the nerve-trunks may become angulated with resulting stretching. Clausen holds that the tendinous arch formed by the insertion of pectoralis minor into the coracoid, by acting as a fulcrum in this way, is in part responsible. If the shoulder girdle is not allowed to rotate—e.g., by impact against a shoulder-rest—this may well be so, but the risk of stretching over the prominence of the head of the humerus in the axilla seems to us much more real. This was, in fact, noted by Clausen as a possible source of trouble, and was mentioned by Halstead as long ago as 1908.

When the humerus is abducted in lateral rotation, its head certainly forms a well-marked prominence in the axilla round which the nerve-trunks must pass as they run laterally across the subscapularis muscle. (This is often clearly seen during the axillary dissection in a radical mastectomy.) Now, this is just the position in which the arm is most often placed when an intravenous infusion is being given—i.e., abduction to 90°, often behind the coronal plane (if it is secured to an arm-board tucked in, for example, under the rubber table-cover), the elbow and wrist being extended and the forearm in supination.

What happens now, if with the arm in this position the patient is placed in a head-down tilt? In the Trendelenburg position we have what really amounts to a forcible pulling down of the shoulder girdle. In fact, the shoulders (and sometimes the wrists, too) are secured to the table, and that component of the body-weight which is all the time tending to push the patient downwards off the table is counterbalanced by the structures which sling the shoulder girdle from the trunk, and among these must be counted the nerve-trunks. The steeper the Trendelenburg tilt and the heavier the patient the greater this component will be; and the longer the position is maintained the longer it will operate.

Most of the strain is probably borne in a conscious person by the tonic contraction of the sling muscles of the shoulder girdle, especially by trapezius and the rhomboids, which together maintain the upper limb, for a time at least, in its normal relationship to the vertebral column. This was certainly true on the one occasion when we investigated this question in a healthy volunteer. A radiogram was taken of the root of the neck and of the shoulder girdle, first with the volunteer recumbent in the horizontal position, and then with the table at a Trendelenburg angle of 30° or thereabouts, the position of the tube in relation to the table remaining unchanged throughout. We had hoped to demonstrate some degree of depression of the shoulder but in this we were disappointed.

Conditions are, however, quite different in a conscious healthy volunteer from those in a deeply anæsthetised patient placed in the same position for a period which may amount even to several hours. I have not had an opportunity of taking comparable radiographs on the operating-table.

It is not unreasonable, however, to suppose that, during a long operation, the muscles, if not already rendered completely flaccid by the depth of anæsthesia, will soon become tired out if they are called on to withstand an excessive strain for too long. As they yield, some of the tension will be exerted on other structures, among them the vulnerable nerve-trunks.

When, in the early days of major abdominal surgery (in the 'nineties or thereabouts), these cases were first noticed, it became the custom to explain them away as being due to the particular narcotic agent then in vogue. There was, however, no real evidence against any of those agents, and we have no reason now to suspect that any of the newer anæsthetics are at all to blame. It does seem, however, that curare and its derivatives have been largely responsible for the increased prevalence of these injuries in recent years. This view has also been expressed by Slocum et al. (1948). The complete generalised muscular flaccidity which this valuable adjunct to general anæsthesia can achieve seems almost certain to increase the risk of tension on the nerve-trunks, as the trunk telescopes up between the restrained shoulders in the Trendelenburg position. It is noteworthy that in each of my cases the patient had received at least one dose of curare.

It might be anticipated that this complication would be especially frequent in patients who were overweight, but this was not the case, either in my experience or in Clausen's. It is interesting, however, that all of my cases were submitted to a long operation, and the shortest operation in Clausen's series took 2½ hours.

The tendency of the head-down tilt position to cause forcible depression of the shoulder girdle will have the effect of rendering still more evident the prominence formed by the head of the humerus. Moreover, in the Trendelenburg position we not only have abduction but we have abduction with a shoulder girdle which cannot readily rotate, so the acromion acts as a fulcrum pushing the humeral head still further down into the axilla. Nor is this all. In the course of an interesting operation (and this is especially true of a teaching hospital) there may well be a press of energetic assistants or of over-curious spectators who, in their eagerness to see what is going on, wedge themselves firmly in towards the operation field and convert the initial arm/trunk angle of 90° into something dangerously greater. With a double arm-board there is a similar danger when the opposite arm is thoughtlessly pushed into adduction.

Add to all this the forcible drawing (by the anæsthetist this time) of the patient's head and neck to the opposite side, and it is surely little wonder that plexus injuries occasionally occur—in fact, one wonders why they do not occur more often.

It has been suggested that the main risk of abduction of the arm when shoulder-rests are accurately in position is that of displacement of the whole trunk towards the abducted side, so that the shoulder-rest comes to press against the trapezius and the plexus (Slocum et al. 1948). I do not consider this an important mechanism in the causation of these nerve injuries.

But paralysis occurs after operations in the Trendelenburg position during which the arms have at no time been abducted. It is interesting that in case 5, in which the paralysis was bilateral, it was more severe, more extensive in its distribution, and also considerably slower in its complete recovery on the side of the abducted arm.

Paralysis also follows operations in which the table has remained throughout in the horizontal position, as in case 3. Its occurrence has been reported, too, after thoracic operations conducted with the patient lying on one side and with the uppermost (and subsequently affected) arm drawn up in full abduction (and usually in these cases in internal rotation) beside the patient's head (Clausen 1942), or even in the supine position with one or both arms drawn up in this way.

Turney (1899), in an admirable communication on this subject to the Society of Anæsthetists, said that such paralysis "depends on the nefarious practice of dragging the patient's arm or arms forcibly over his head, sometimes for convenience in feeling the pulse, but more often to get the limb out of the way of the surgeon." He was of the opinion that, with the arm in this position, the plexus became compressed between the clavicle and the scalene muscle or the first rib.

I believe that in all these circumstances the mechanism is likely to be the same—i.e., tension or overstretching of the plexus. In a patient whose back is extended over a double gall-bladder wedge and with his arms bound back in the crucifix position to a double arm-board, stress on the nerve bundles certainly is not unlikely.

Examination of the cadaver seems in some measure to support the above hypothesis, though

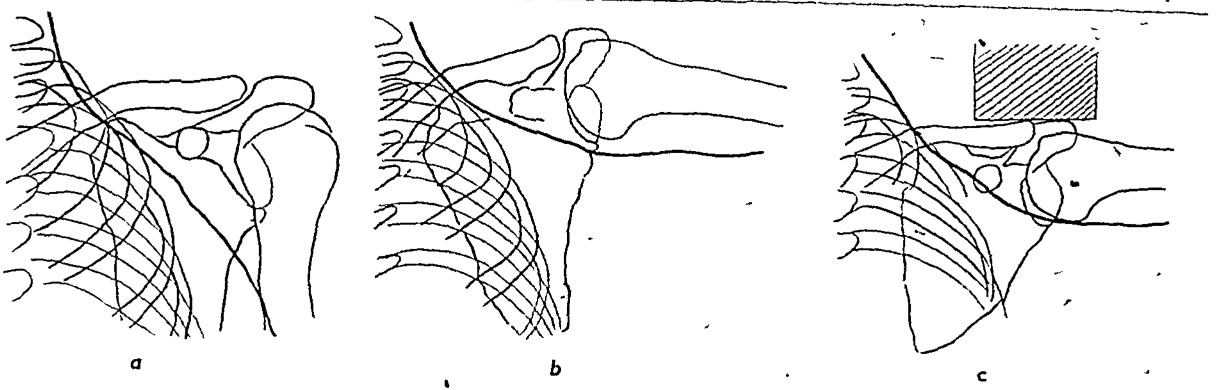

Fig. 1—Relation of brachial nerve-trunks (black line) to head of humerus in different positions of arm: *a*, arm adducted; *b*, arm abducted, extended, and laterally rotated; *c*, as in *b* but with weight applied to acromion.

makes the value of any such observations less real. The plexus and the main nerve-trunks in the axilla can be *fairly freely* exposed by three short incisions—one just above the clavicle, one along the lateral wall of the axilla, and a third, between these two, parallel with the fibres of pectoralis major, which can be gently separated with the blunt end of a scalpel. This exploration does not involve any considerable division of muscle, and it is possible in this way not only to feel but also to see how the nerves lie in different positions of the arm.

Downward *traction on the adducted arm seems to* put the plexus under some tension, but there is no sign in this position of the angulation over the first rib which Clausen believed to be important. The tightness of the nerve-trunks is, however, much greater when the shoulder is abducted and laterally rotated with the elbow in extension, and there now becomes clearly apparent the prominence of the humeral head in the axilla round which the nerve-trunks are seen to be stretched. At the prominence of this curve it is the musculo-cutaneous nerve which lies most closely against the subscapularis cushion, and the *apparent frequency of its involvement* in our cases (cases 1 and 2) may well be related to its position at this point. As the degree of abduction is increased (the arm still being held in full lateral rotation) so the tension mounts.

When, in addition to abduction, lateral rotation, and extension of the shoulder, the acromion was forcibly pushed caudally, the plexus and nerve-trunks became as tight as bow-strings. They seemed, in fact, as they crossed the unyielding fulcrum formed by the humeral head, to be bent as one would bend a green stick across one's knee. Extension of the head and neck to the opposite side did not seem to make matters noticeably worse.

With the arm in full abduction the clavicle falls backwards against the first rib, but any pressure on the plexus in this position is inconsiderable: in full adduction this space becomes opened out.

I have tried to record these observations radiologically by outlining the upper limit of the plexus and the line of the major nerve-trunks in the axilla with malleable wire secured by Michel clips, or with clips alone. Figs. 1 and 2 are tracings of radiograms obtained in this way. In fig. 1*a* the arm was lying adducted by the side; in fig. 1*b* it was brought out into abduction, extension, and full lateral rotation at the shoulder, the elbow being extended. The corrugations of the wire at this stage became rather less evident, but it was only when firm downward pressure was applied through a wooden block against the acromion that the fulcrum action of the humeral head against the plexus became apparent (fig. 1*c*).

Similar findings were obtained in a second cadaver, but in a third cadaver abduction of the arm did not stretch the plexus unduly; in fact, the plexus seemed to slip forwards across the anterior aspect of the rotated humeral head (fig. 2).

Most of the patients who develop these complications are women. This might suggest that there is some peculiarity in the arrangement of the nerves or in the configuration of the bony skeleton which renders the female plexus especially liable to this type of injury. It used to be said that "cervical rib" is more common in women, and it is still true that the "costoclavicular syndrome" (as it is now the fashion, maybe less in*correctly, to style the same complaint)* is more common in women. This is probably because in the female the shoulders are naturally more drooping than in the male and *that* this often becomes *pathological* in degree when the muscles supporting the shoulder girdle are overtired. Some of these arguments might also be put forward to explain the apparent high percentage of postoperative plexus injuries in women. I feel sure, however, that this high frequency is not so much related to structural abnormalities but is rather a direct result of the high proportion of gynæcological operations done in the Trendelenburg position. The reported high percentage of cases after pelvic operations can be similarly explained.

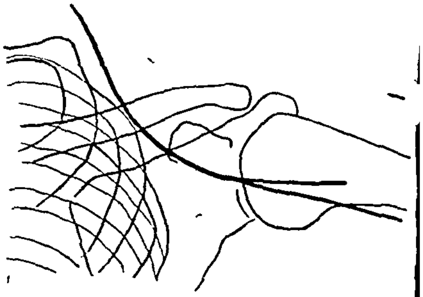

Fig. 2—Position as in 1b, but brachial plexus has slipped across head of humerus, avoiding pressure.

Prognosis

Complete recovery in these cases seems to be almost the rule but it may, as in our patients, take some months. The paralysis is predominantly motor, and the lesion is one of neurapraxia or of axonotmesis and never of neurotmesis. The upper part of the plexus is most commonly involved, but lesions affecting the 8th cervical and 1st dorsal root have also been reported.

Prevention

The prevention of this distressing postoperative complication involves avoiding, so far as possible, all the conditions which favour the development of the mechanisms of injury which I have elaborated above.

We must particularly anticipate trouble when the operation is a long one in the Trendelenburg position, the more so if curare is used as an aid to muscular relaxation. In no circumstance must the arm be abducted with the patient in this position. If it seems ikely to be necessary, a needle or cannula with a generous length of rubber tubing should be inserted into an arm vein (preferably one on the dorsal aspect of the wrist or forearm) before the operation begins, so that the arm can then safely be folded across the chest or tucked out of the way under the towels down by the side. Alternatively, use can be made of a convenient vein somewhere round the ankle.

In fact, wide abduction of the arm for long periods is to be avoided during any operation, and the arm should never be secured in extension to a single or, worse still, to a double arm-board. If it becomes urgent to bring the arm out from the side, whether for venoclysis or for the application of a sphygmomanometer cuff, care must be taken not to hold it in lateral rotation and with a fully extended elbow and supinated forearm.

Hyperabduction of the arm, too, must be studiously avoided, as should any manipulations under full anæsthesia which involve a sustained pull on the arm even in the adducted position.

Padding of the shoulder-rests alone, however desirable, will not prevent these paralyses, nor will the fashioning of *any alternative yoke*, however carefully it may be designed to fit the shoulders. Securing the wrists to the table is no better; what is wanted is some method of preventing the patient from slipping down the table which will act not from the upper arm to the trunk through the agency of the sling mechanism of the shoulder girdle. We can, of course, for some operations—and this is probably the practice in most gynæcological clinics—break the table and flex the knees, but undue pressure on the calf is undesirable as likely to increase the risk of deep venous thrombosis. It is not readily possible to adopt this manœuvre in a rectal excision, more especially since it is not our practice in most cases to do a synchronous combined abdominoperineal operation using the Lloyd-Davies leg supports. No doubt they contrive in some measure to prevent the patient from slipping down the table, but it seems that something more is needed. We now take good care not to tilt the table much down by the head, and recently we have taken to inserting under the upper part of the sacrum a thin but long sausage-shaped sandbag secured to the foot of the table; this seems to help considerably in preventing the trunk from pressing downward too hard against the shoulder-rests. If these accidents should unhappily continue, it may be necessary to devise some method of utilising the iliac crests as points of pressure, or of securing the thighs to the uprights of the leg supports.

SUMMARY

Five cases of upper-arm paralysis following operation are reported.

In two patients there was a partial brachial plexus lesion, and in one of them it was bilateral.

Recovery was in all cases almost complete within a few months.

The wide use of curare may be partly responsible for the present prevalence of this complication.

The various mechanisms of this injury are discussed, and some evidence is given that in this respect abduction of the arm in the Trendelenburg position is a particularly dangerous manœuvre.

My thanks are due to Prof. Ian Aird for his helpful criticism and to Dr. Duncan White for the X-ray photographs.

BRACHIAL PLEXUS LESIONS AFTER CHOLECYSTECTOMY

Leslie G. Kiloh
M.D., B.Sc. Lond., M.R.C.P. D.P.M.
NEUROLOGICAL REGISTRAR, KING'S COLLEGE HOSPITAL, LONDON

Lesions of the peripheral nervous system arising during anæsthesia are by no means uncommon. When the peripheral nerves themselves are injured, the mechanism is usually clear, and the relation of the damaged nerve to some source of pressure is apparent. The brachial plexus too is susceptible to injury but the factors involved are less obvious.

Büdinger (1894) published the first description of brachial-plexus lesions occurring during anæsthesia, and further cases were described by Krumm (1895), Garriques (1897), Horsley (1899), and Green (1902). In recent years relatively little attention appears to have been paid to the condition, but Clausen (1942) reviewed 9 cases and discussed the possible causes.

In most of the cases described, the lesion has been associated with the use of the Trendelenburg position. Injuries to the plexus are less common in other positions and consequently their occurrence is less widely recognised. Those following cholecystectomy show this same numerical relationship to the Trendelenburg position, though Clausen reports an example in which the operation was done in the horizontal supine position.

The present short series of cases occurred in two hospitals during a period of a year. They are described to draw attention to this disabling postoperative complication, which in spite of improvements in surgical and anæsthetic techniques still occurs too frequently.

Case 1.—A man, aged 66, had a cholecystectomy on Jan. 17, 1949. He was given 1·4 g. of thiopentone and 35 mg. of tubocurarine chloride, and anæsthesia was maintained with cyclopropane and oxygen. The patient was in the horizontal supine position and a gall-bladder rest was used. His arms were abducted to about 90° and during the operation a pint of saline and a pint of blood were given intravenously into the right arm. The operation lasted 135 minutes.

On his recovery from the anæsthetic the man's right upper limb was totally paralysed. The deep reflexes were lost but there was no sensory impairment.

Ten days later considerable recovery of power had occurred. He could abduct the arm to 90° but all movements were still weak. He now complained of pain in the right shoulder, radiating down the outside of the arm to the wrist. The muscles were tender.

Seven months after operation he still had difficulty in his work, which involved lifting heavy weights. He also complained of an aching pain in the upper arm and the muscles were tender. There was slight wasting of the volar aspect of the right forearm with slight weakness (4 to 4 + on the Medical Research Council scale) of the deltoid, supraspinatus, extensors of the wrist, supinators, pronators, the long flexor of the thumb, the thenar muscles, and the dorsal interossei. The deep reflexes in the two arms were equal and there was no sensory loss. X-ray films of the cervical spine showed no abnormality. It was difficult to obliterate the radial pulses, and in this respect there was no difference in the two arms.

In this case there was a complete brachial-plexus palsy without sensory loss. Initially recovery was rapid, but even after seven months it was not complete.

Case 2.—A man, aged 31, had a cholecystectomy on June 13, 1949. He received 'Omnopon' gr. $^1/_2$, scopolamine gr. $^1/_{150}$, and tubocurarine 45 mg., followed by gas, oxygen, and ether. The horizontal supine position was used, with a gall-bladder rest. The arms were abducted to about 90° in the plane of the trunk or a little behind it and externally rotated. In this case, and in case 3, a "gall-bladder harness" was used to maintain the position of the arms; this consists of two adjustable leather cuffs, joined by a piece of padded chain which, when the harness is in use, passes behind the patient's neck. The operation lasted 80 minutes.

On his recovery from the anæsthetic the man was found to have profound weakness in both arms, more marked on the right.

Next day he complained of pins and needles in both hands. Power began to return in both arms, but seven days after the operation examination revealed considerable weakness in all the muscles innervated via the two brachial plexuses, with the exception of the rhomboids. In general the weakness was greater on the right. The infraspinati (Rt 3 +, Lt 4), deltoids (Rt 2, Lt 4), triceps (Rt 3, Lt 4—), and small muscles of the hands (Rt 3 +, Lt 4) were particularly affected, and the muscles were all flabby and tender. The deep reflexes were absent in both arms but there was no sensory loss. There was well-marked tenderness over both plexuses. The radial pulses could be obliterated easily when the arms were abducted, but there was no radiological abnormality of the cervical spine. Ten days after the operation he complained of pain across the shoulders and down both arms to the elbows, which kept him awake at night. By five weeks after the operation, considerable recovery had occurred and the deep reflexes had returned.

Four months after the operation there was slight residual weakness of the extensors of the right wrist and fingers. He still complained of an aching pain in the upper right arm and the muscles were still tender.

This patient had a partial lesion of both brachial plexuses in which all roots were involved but without sensory loss. After four months, recovery in the left arm was complete and that in the right arm almost so.

Case 3.—A woman, aged 20, had a cholecystectomy on May 12, 1949. She was given thiopentone 0·65 g., 'C10' 7 mg., cyclopropane, and oxygen. Both a gall-bladder rest and a gall-bladder harness (see case 2) were used. The operation was performed in the horizontal supine position with the arms abducted to about 70° in the plane of the trunk and externally rotated. It lasted 75 minutes.

On her recovery from the anæsthetic the patient complained of gross weakness and numbness of the left arm.

After three days sensation began to return down the medial side of the arm and to the medial three fingers. Eight days after the operation she complained of a burning pain in the left shoulder and down the outer aspect of the limb to the thumb and index finger. There was considerable weakness of all muscles innervated by the left brachial plexus with the exception of the rhomboids, serratus anterior, and latissimus dorsi. The spinati (3), deltoid (2 +), biceps (3), and the small muscles of the hand (3 +) were affected more severely than the others. The deep reflexes were absent and there was some impairment of superficial sensation in the distribution of segments C5 and 6. The muscles were flabby and tender. The left thumb and index finger and brachial plexus were particularly tender. X-ray examination of the cervical spine revealed no abnormality. The left radial pulse could be obliterated easily with the arm abducted to 90° in the plane of the trunk. The right radial pulse was more difficult to abolish. Six weeks after the operation there was slight but definite wasting of the left thenar eminence, first interosseous space, forearm muscles, triceps, deltoid, and pectorals. Moderate weakness was still present. The deep reflexes were still absent but the sensory impairment was now confined to segment C6.

Five months after the operation only minimal wasting of the volar aspect of the forearm and first interosseous space was still evident, and, apart from slight weakness of extension of the wrist, power was normal. The deep reflexes had returned and there was no longer any sensory loss. She complained only of a tight feeling in her left arm and some tenderness of the left thumb. She could now type as well as before the operation but was disinclined to carry heavy weights.

In this case there was initially severe involvement of all roots of the brachial plexus. Recovery was virtually complete within five months.

Case 4.—A woman, aged 42, had a cholecystectomy on May 25, 1949. She was given 0·5 g. of thiopentone, 30 mg. of tubocurarine, cyclopropane, and oxygen. A gall-bladder rest was used. The left arm was abducted to 90°. At first the right arm was placed in the same position but later it was extended and externally rotated in addition. A pint of saline was given intravenously into the left arm during the operation, which lasted 80 minutes. On her recovery from the anæsthetic the patient was found to have a complete flaccid paral the right upper limb with a corresponding sensory loss.

Two weeks later the deltoid, spinati, pectorals, latis dorsi, biceps, brachioradialis, and triceps muscles were weak (3 —). The extensors of the wrist and hand (flexors (4), and small muscles of the hand (4 +) were less se affected. The deep reflexes were absent but the sensor was now confined to the area supplied by C5. Five after the operation considerable recovery had occurred b deltoid and spinati (4 —) were still weak enough to requi use of an abduction splint. The deep reflexes and se loss were unchanged.

Five months after operation the patient complained of a slight aching in her right shoulder. There was no ness or sensory loss, and the tendon reflexes in the two were equal.

This case showed a complete brachial-plexus l with sensory loss. The muscles supplied by the l roots recovered more rapidly than the others, but reco was complete in five months.

DISCUSSION

The occurrence of postoperative brachial-plexus les has been recognised for many years, but there is no gen agreement on their cause. The earlier workers ascri the damage of the plexus to pressure. Büdinger (1 contended that the lesion resulted from compres of the plexus between the clavicle and the first Krumm (1895) believed that in his cases the plexus compressed between the clavicle and the transv processes of the fifth and sixth cervical vertebræ, w Braun (quoted by Garriques 1897) thought that pres might be exerted on the plexus by the head of humerus when the arm was extended and extern rotated. An unquestionable example of a brach plexus lesion due to pressure is that related by Clau (1942), in which an inadequately padded shoulder impinged directly on the plexus of a patient in Trendelenburg position.

The alternative explanation, that the injury is due traction, was first advanced by Gerdy (quoted by Clau 1942). Horsley (1899) and others supported this vi and the more recent work of Stevens (1934) also favours The brachial plexus is fixed at each end, proximally, the level of the transverse processes by the preverteb fascia and distally by the axillary fascia. Tension in t plexus will develop therefore when distraction occ between these two attachments. A lesion following fall on the point of the shoulder is the most obvio example of this. Horsley (1899) indeed, by droppi cadavers on their heads so as to cause violent later flexion of the head and depression of the shoulder, show that actual disruption of the plexus could be produce Less severe but strictly comparable lesions of the plex may follow excessive lateral flexion of the neck of anæsthetised patient lying on his side.

Tension in the plexus may also be produced by placi the arms and neck in certain positions. In its course fro the neck to the arm, the plexus passes deep to the insertio of pectoralis minor into the coracoid process. Steven (1934) pointed out that this insertion acts as a pulley and that if the coracoid process is depressed the stra will fall on the upper roots of the plexus, whereas if it is raised the lower roots will suffer. When the arm abducted, extended, and externally rotated the head o the humerus becomes prominent, displacing the plexu forwards.

In 3 of the 4 cases described here, the affected lim (in 1 case both limbs) was abducted, extended, an externally rotated, while in the fourth it was abducte and extended only. These are positions which th anatomical studies quoted above have shown to b dangerous. Compression is likely to occur, the clavicl and first rib being the principal effective agents, an stretching of the plexus is inevitable. The theorie of pressure and traction are not mutually exclusive pure examples of each have been quoted from the published reports, but in most cases both play their ombined parts in varying degree.

Subsidiary factors, such as postfixation of the plexus, ervical ribs, or hypertrophied scalene muscles, which might be expected to predispose to plexus lesions, were not found in the cases described. The depth of anæshesia, with its resulting relaxation and loss of guarding muscle tone, is likely to influence the outcome, but the importance of this factor is extremely difficult to estimate accurately. It is noteworthy that all of the 4 patients discussed were given curare or allied drugs. In the same year 4 further cases of brachial-plexus palsies have been seen following the use of the Trendelenburg position, but they are not described in greater detail because this association is well recognised. They too, however, all received curare-like drugs. The frequency of these plexus injuries appears to have increased since the introduction of these substances into general anæsthetic practice.

Lastly there is the question of individual idiosyncrasy—perhaps the most important factor of all. The slope of the shoulders, the size of the cervico-axillary canal, the shape of the first rib, and other individual anatomical peculiarities, all within the limits of normality, may in combination render the brachial plexus vulnerable to pressure or traction.

It is unfortunate that in cholecystectomy the arms cannot be placed alongside the body if a gall-bladder rest be used, because of the danger of producing a lesion of the ulnar or radial nerve; such mishaps have been reported by Mullen (1939). Nor is the surgeon very willing to permit the hands to be folded across the chest, because they are liable to obstruct the field of operation. Some compromise is necessary between the surgeon's demands and the danger of damaging the patient's brachial plexus. The vulnerable position of the arms can be maintained in the great majority of patients without danger but an unpredictable few will develop a palsy. Safety can almost be guaranteed by keeping the arms adducted to the side with the forearms flexed and the hands supinated in front of the shoulders. This position can be achieved and maintained by applying the gall-bladder harness already described, taking care that the elbows are kept well into the side of the trunk. Briefly, safety can be ensured by avoiding such positions as produce discomfort in a conscious person.

Fortunately the prognosis in these cases is good and the 4 patients described have almost completely recovered. A persistent disability which may outlast the weakness is an aching pain in root distribution, associated with tenderness of muscles and in one case with tender finger-tips.

SUMMARY

Four cases of brachial-plexus lesions noted immediately after cholecystectomy are described.

The possible factors underlying the production of brachial-plexus lesions during anæsthesia are reviewed. The two main theories of their causation—pressure and traction—are not mutually exclusive, and in most cases the plexus has probably been submitted to both. The horizontal posture in itself is no safeguard against brachial-plexus lesions, and abduction of the arms, particularly when associated with extension and external rotation, is potentially dangerous.

The greater relaxation obtained with curare and similar drugs may in part be responsible for some increase in the incidence of brachial-plexus injuries.

I should like to thank those members of the staffs of King's College Hospital and Dulwich Hospital who have allowed me access to their cases. In particular I should like to express my gratitude to Dr. S. Nevin for his help and suggestions.

SENIOR REGISTRARS, ROYAL INFIRMARY, MANCHESTER

From the Department of Cardiology, University of Manchester

AURICULAR flutter was first differentiated from other types of arrhythmia by Jolley and Ritchie (1911). It has since been studied by many workers; in particular the physiopathology by Lewis (1912) and the clinical and therapeutic aspects by Parkinson and Bedford (1927). Our purpose is to discuss the ætiological factors, therapeutic results, and electrocardiographic features in 36 cases.

MATERIAL

Material for this study was selected from cases seen during recent years either in the department of cardiology of the Manchester Royal Infirmary or by Prof. Crighton Bramwell privately. Since a satisfactory definition of auricular flutter can only be made in terms of electrocardiography, we have included only cases in which the electrocardiogram showed constant and regular auricular activity with even spacing of the flutter or F waves. Neither the rate of auricular activity nor the amplitude of the F waves was regarded as important; for, though the auricular rate is usually more rapid, and the F waves smaller, in auricular fibrillation, this is not invariable, and no clear dividing line can be made on these grounds between the two arrhythmias.

Auricular flutter is usually divided into paroxysmal and permanent types. Parkinson and Bedford (1927) regarded flutter of less than fourteen days' duration as paroxysmal, whereas Blackford and Willius (1918) included under this heading only those cases in which there were paroxysms of palpitation lasting minutes or hours. Clinically it is impossible to distinguish paroxysms due to the onset of flutter from changes in the ratio of auricular to ventricular response occurring in cases of established flutter; for this reason we have not tried to divide our cases into paroxysmal and permanent types.

INCIDENCE OF AURICULAR FIBRILLATION AND FLUTTER AND RATIO OF FIBRILLATION TO FLUTTER

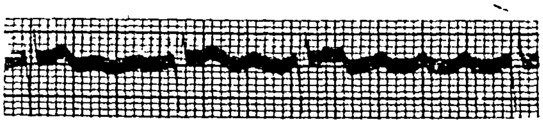

Fig. 1—Electrocardiogram (lead III) from a case of auricular fibrillation in which, for short periods, auricular activity is slow and regular, and which may therefore be confused with flutter.

examined electrocardiographically and 16 cases of auricular flutter were found. The incidence per 1000 cases, together with the incidence of auricular fibrillation, both in other workers' series and our own, is shown in the accompanying table. We were surprised to find that the flutter-fibrillation ratio in our series was much lower than that usually found, but this may be due to our criteria of selection, which exclude those cases of "impure flutter" in which auricular activity, though irregular, is sufficiently slow to cause confusion. Fig. 1 is an electrocardiogram (lead VR) from a case of auricular fibrillation of this kind, in which, for short periods, auricular activity is so slow and regular that it closely simulates flutter.

ÆTIOLOGY

Cases in which there was unequivocal clinical and radiological evidence of mitral stenosis were classified as rheumatic. Those with a persistent diastolic blood-pressure of 110 mm. Hg or more; with cardiac pain on effort; with clinical or electrocardiographic evidence of myocardial infarction; or with cardiac enlargement for which no other cause could be found, combined with peripheral arteriosclerosis, were classified as degenerative. The remaining cases were classified as miscellaneous.

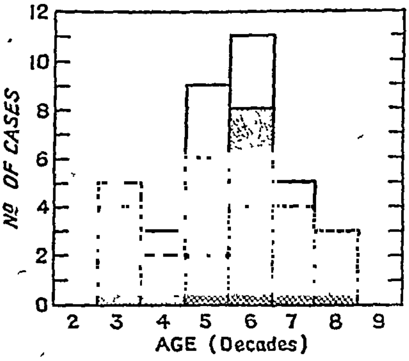

Fig. 2—Age-incidence and ætiology in 36 cases of auricular flutter: stippled columns, rheumatic; hatched columns, degenerative and hypertensive; blank columns, miscellaneous.

On this basis 14 cases were classified as rheumatic, 13 as degenerative, and 9 as miscellaneous. This last-named group comprised 2 patients with a history of rheumatic fever but no evidence of a valvular lesion; 2 with congenital heart-disease (1 pulmonary stenosis, and 1 an intra-atrial septal defect); 2 convalescent (1 after drainage of an empyema and 1 after pneumonectomy for a carcinoma bronchus); 1 thyrotoxic; 1 with active rheumatoid arthritis; and 1 case with a negative medical history and no objective evidence of heart-disease. In view of its interest this last case is reported here.

Case 1.—A clergyman, aged 45, was admitted to hospital on Dec. 28, 1934, with two weeks' history of palpitations and a rapid irregular heart action. He had had similar but shorter attacks on two previous occasions, in 1921 and 1923. His previous health had otherwise been excellent.

On examination the pulse was regular, rate 130 per min. The heart was clinically normal and the blood-pressure 105/70 mm. Hg. Radiography showed a heart of normal size and bilateral cervical ribs. The electrocardiogram showed auricular flutter with a 2:1 ventricular response.

Treatment was begun with digitalis, min. 735 of the tincture being given in 18 days without causing any change in the rhythm. A course of gr. 45 of quinidine was then given over 3 days without benefit, and the patient was discharged in January, 1935, on a maintenance dose of 'Digitalin Nativelle' gr. $^{1}/_{400}$ daily. The electrocardiogram still showed auricular flutter.

Follow-up.—In July, 1935, an electrocardiogram a normal sinus rhythm. In January, 1948, the wrote that he was symptom-free apart from occ bouts of palpitation.

The only abnormal findings in this case, apart fr arrhythmia, were bilateral cervical ribs, but it is i able that this abnormality was related to the condition. There was no clinical evidence of toxicosis but, since the patient was in the fifth when first seen, the possibility of degenerative disease cannot be excluded.

Fig. 2 shows the age-incidence and ætiology. greatest incidence is in the fifth and sixth decades, rheumatic heart-disease predominating in the younger age-groups, and degenerative and hypertensive disease in the elder.

The sex-incidence is 29 males to 7 females; this preponderance is partly explained by the liability of the male sex to degenerative c vascular disease, for all 13 cases in the degene group were in men.

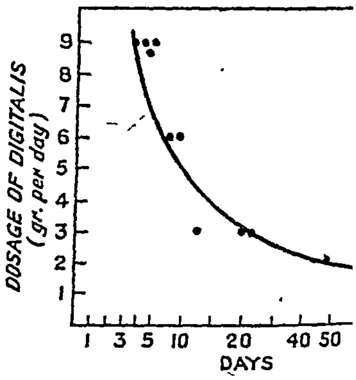

Fig. 3—Relation of dosage of digitalis to d of treatment before fibrillation superv 11 cases.

TREATMENT AND RESULTS

Digitalis alone was used in 14 cases, normal rh being induced in 8 (but 2 subsequently reverted to flu fibrillation supervening in 4, and flutter persisting in

In a further 9 cases treatment was initiated digitalis, fibrillation being induced in 4, and f persisting in 5. Quinidine was given to all 9 cases of the 4 which were fibrillating 1 regained normal rhy 2 reverted to flutter, and 1 continued to fibrillate. rhythm did not change in the 5 patients with persi flutter. Digitalis was continued in each case other the one converted to normal rhythm, and ultim normal rhythm was obtained in 3, persistent fibrill in 2, and the flutter continued in 3.

Quinidine alone was used in 3 cases, normal rhy being obtained in 1, and flutter persisting in the 2 ot

Thus, of 23 cases, digitalis caused normal rhyth be restored in 11 and induced permanent fibrillation Quinidine, given together with digitalis to 9 of patients, was responsible for restoration to no rhythm in 1. When quinidine was used alone further 3 cases, normal rhythm was restored in 1 and flutter persisted in the 2 others.

We found that the rapidity with which fibrillation could be induced varied with the dosage of digitalis used. In 5 cases given gr. 3 of the powdered leaf eight-hourly the change in rhythm occurred on the fourth da 4 (flutter persisted in the fifth), whereas in cases trea with only gr. 2 or 3 daily up to three months was necess In 11 cases electrocardiograms were taken often eno

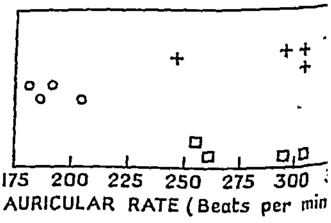

Fig. 4—Effect of digitalis and quinidin rate of auricular activity in 4 case persistent flutter: circles, after quinid crosses, after digitalis; squares, untre

or us to know when flutter changed to fibrillation and he time interval related to the dosage in these cases s shown in fig. 3. Fig. 4 shows the effect of digitalis and quinidine on the rate of auricular activity in 4 cases in which flutter persisted. The slowing produced by quinidine may permit a 1 : 1 ventricular response with the attendant risk of heart-failure; this happened in the following case.

Case 2.—A married woman, aged 58, was admitted to hospital on Feb. 28, 1947, with five months' history of palpitation and two years' history of attacks of rapid heart action, the longest having lasted nine months. She had had rheumatic fever at the age of 19.

On examination the pulse was irregular, rate 94 per min. There were no murmurs, but a third heart sound was audible at the apex. The blood-pressure was 150/90 mm. Hg. Radiography showed enlargement of the pulmonary conus and the left auricle. The electrocardiogram showed auricular flutter with a varying 4 : 1 ventricular response (fig. 5, upper record).

Treatment with digitalis gr. 1 t.i.d. was begun on March 3, but on the 13th flutter still persisted; so digitalis was discontinued. On March 18 quinidine was given in doses of gr. 6 two-hourly; but after the second dose severe palpitation and dyspnœa developed owing to a 1 : 1 ventricular response, the rate being 212 per min. (fig. 5, lower record). Quinidine was stopped, and digitalis was restarted in a dosage of gr. 3 daily and continued until March 24. Quinidine therapy was begun again on March 25, and gr. 90 was given in three days without causing distress but without affecting the arrhythmia.

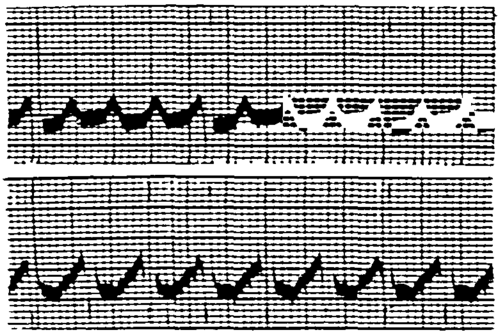

Fig. 5—Electrocardiograms (both CRI) from case 2: upper record, taken before treatment was begun, shows 4 : 1 ventricular response, auricular rate being 230 per minute; lower record, after gr. 12 of quinidine had been given, shows 1 : 1 ventricular response at a rate of 212 per minute.

Progress and Follow-up.—Flutter persisted, and the patient was discharged on April 2 on a maintenance dose of digitalis and feeling reasonably well. On July 3 she was symptom-free and well-controlled fibrillation was present.

It will be observed that in this case quinidine was tolerated only when the patient was fully digitalised.

In 10 of our 36 cases the therapeutic notes were insufficient to enable us to draw any conclusions.

ELECTROCARDIOGRAPHY

Auricular activity may not be shown equally well in each of the various leads. Of the bipolar limb leads we have found that lead II or lead III is the most satisfactory, but better records are often obtained with leads from the right præcordium.

Heard and Strauss (1917) noted that in some of their cases there was an iso-electric phase between each flutter wave, but Lewis (1912) had previously observed that auricular activity was continuous. We could not confirm the findings of Heard and Strauss, and have found that, though in one lead each auricular wave may be apparently discrete and separated from the adjacent wave by an iso-electric phase, a different lead taken immediately after will show continuous auricular activity. Fig. 6 shows serial leads (III and V₁) from a case of auricular flutter in which continuous auricular activity is evident in lead III, but the F waves are discrete in V₁. The auricular rate is 240 per minute.

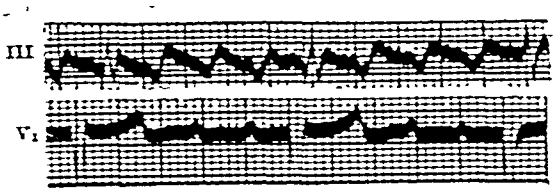

Fig. 6—Consecutive electrocardiograms (leads III and V₁) from a case of auricular flutter. Auricular activity is continuous in lead III, though in lead V₁ the F waves appear discrete and separated from each other by an iso-electric period.

In most cases we noted a constant time relation between the beginning of each ventricular complex and the preceding F wave, but occasionally there seemed to be a varying block and this relation was lost. Fig. 7 shows lead-III electrocardiograms from 2 cases illustrating this point.

DISCUSSION

The ætiological factors in our series correspond closely to those found by other workers (Ritchie 1914, Blackford and Willius 1918, Keating and Hajek 1922, Parkinson and Bedford 1927, Campbell 1947). All found evidence of organic heart-disease in 90% of cases, and the ætiology closely corresponds to that which White (1944) found in a large series of cases of auricular fibrillation. By contrast, in paroxysmal supraventricular tachycardia organic heart-disease is absent in 50% of cases (White 1944). Various workers (Wedd 1924, Parkinson and Bedford 1927, White 1944), have commented on the rarity of flutter in subacute bacterial endocarditis, acute rheumatic fever, and other febrile infections; we have not observed it in 60 cases of subacute bacterial endocarditis.

Our experience suggests that digitalis is the drug of choice, and our percentage of successful results corresponds closely to those of Blackford and Willius (1918) and Parkinson and Bedford (1927). We think it is important that full dosage should be used, not only because of the rapidity with which fibrillation may be induced but also because with small doses there is the danger that fibrillation, when it arises may not be adequately controlled. For this reason we did not withdraw digitalis when fibrillation arose, but we continued a maintenance dose indefinitely or, in successful cases, until normal rhythm supervened.

Quinidine we found to be ineffective, influencing the rhythm in only 2 of 12 cases. It is not without risk, but this risk may be minimised by first giving digitalis in full doses. Used in this way it may have a place in treatment; Tandowsky et al. (1946), giving quinidine after fibrillation had been induced with full doses of 1·5 mg. of lanatosid C intravenously, obtained conversion to normal rhythm in 14 out of 15 cases. It may, how-

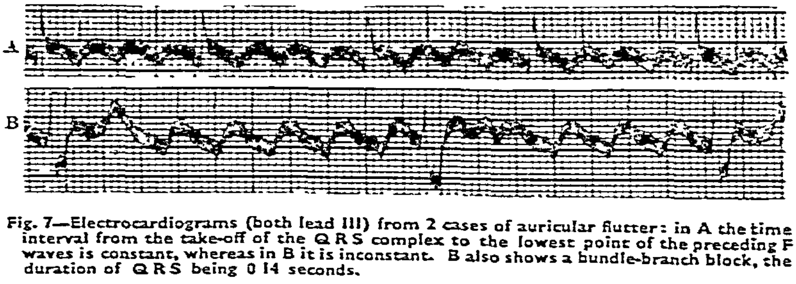

Fig. 7—Electrocardiograms (both lead III) from 2 cases of auricular flutter: in A the time interval from the take-off of the QRS complex to the lowest point of the preceding F waves is constant, whereas in B it is inconstant. B also shows a bundle-branch block, the duration of QRS being 0·14 seconds.

ever, as in 2 of our cases, produce reversion to flutter, and this was also observed by Parkinson and Bedford (1927). Both in their cases and in ours fibrillation was again induced by digitalis but Wolferth (1923) and Viko et al. (1923) have noted the production of a "fixed" flutter resisting all further treatment.

The likelihood of success in restoring normal rhythm does not seem to be related to the severity or type of associated organic heart-disease, an observation made also by *Parkinson and Bedford (1927)*.

We have noted how auricular activity can usually be demonstrated best by leads from the right præcordium. CR leads, in which the indifferent electrode is connected to the right arm, are often superior to V leads, in which the indifferent electrode is connected to a central terminal of about zero potential (Wilson et al. 1932), because the potential changes at the right arm summate with the potential changes at the exploring electrode, thus increasing the amplitude of deflection. With CF leads this effect will only be seen in those cases in which the heart is electrically vertical and consequently the left-arm electrode is facing the cavity of the ventricles.

SUMMARY

The ætiology and treatment, and some of the electrocardiographic features, of 36 cases of auricular flutter, selected by electrocardiography, are reported and discussed.

In 14 cases the ætiology was rheumatic and in 13 degenerative. In the remaining 9 cases various other ætiological factors were concerned.

In the treatment of auricular flutter digitalis is considered to be the drug of choice, normal rhythm having been restored in 11 of 23 cases so treated. The importance of adequate initial dosage is emphasised. *Quinidine has* proved much less effective, and some of its dangers are discussed.

Some features of the electrocardiogram are described.

We wish to thank Prof. Crighton Bramwell, at whose instigation this study was made, for his help and guidance; and Mr. T. Corless for technical help in the preparation of the electrocardiograms.

"... The average working man in this country earns about £7 a week, and the national income presumably benefits by that amount of production whenever he is working. But when he is absent from illness or disability, that sum is lost and he receives in addition some £2–3 from the national exchequer for his maintenance, so that the national income is some £10 worse off for every week that he has to be away. Conversely, for every week that can be saved from his disability period by getting him back to work more quickly and more fit, some £10 is saved to the nation. This means that if you put 500 people through this rehabilitation department of yours and restore them to productive work one week earlier than would otherwise be the case, you will pay the whole cost of running the department; and every patient so restored beyond that figure of 500 will represent a net gain to the national economy."—Dr. HAROLD BALME, opening extensions to the department of physical medicine and rehabilitation, Bolton Royal Infirmary, on Dec. 1, 1949.

ARSINE POISONING IN INDUSTRY

REPORT OF A CASE

MATTHEW STEEL
M.D. Lond., M.R.C.P.
MEDICAL REGISTRAR

D. V. G. FELTHAM
M.B. Camb.
LATE HOUSE-PHYSICIAN

UNIVERSITY COLLEGE HOSPITAL, LONDON

ARSENIURETTED hydrogen, or arsine, is a colourle gas with the odour of garlic. It was first identified b Scheele in 1775, and its toxicity was strikingly demo strated in 1815, when Gehlen, a Munich chemist, die after inhaling it in his laboratory. Since then numero cases of poisoning in man have been described, most them resulting from industrial processes (Jones 190 Glaister 1908, 1913, Hake 1910, Dudley 1919, Wignall 192 Willcox 1922, Legge 1923, Zangger 1930, Bomford an Hunter 1932, Smith and Rardin 1939, Bulmer et al. 194 Hunter 1943, Wilson and Mangun 1943, Hawlick an Ley 1946); but in recent years the incidence has bee very low, and since 1935 only eight cases have bee reported to H.M. Chief Inspector of Factories. No cas has been *so reported since* 1941.

The highest incidence has been in metallurgical indu tries, including the cyanide process for extraction of gol (Jones 1907, Bulmer et al. 1940). Some cases have occurre in the manufacture of aniline dyes (Jones 1907). There h been a surprising frequency among chemists, presumabl due to failure to recognise the extreme toxicity the gas. A curious feature was the incidence in to balloon vendors, and in aeronauts during the ear days of ballooning, as a result of the use of hydrog contaminated with arsine (Glaister 1908, 1913).

Arsine is produced when nascent hydrogen is releas in the presence of arseniferous materials. This occu when water reacts with metallic arsenides, in the Mars test, in the electrolysis of arsenides or arsenic-aci solutions, and in the reaction between mineral aci and metals when either is contaminated with arsenic.

CLINICAL PICTURE

The clinical features of arsine poisoning were describe by Glaister (1908) as general malaise, giddiness, pains i the head and epigastrium, shivering, a sense of oppressio of breathing, sometimes accompanied by cyanosis, nause and vomiting. These are quickly followed by continuou vomiting of bloody material, occasionally diarrhœa jaundice, pain in the loins and hepatic area, hæmorrhages and bloody urine, which may be succeeded by oliguri and anuria. The intellect remains clear, except fo terminal coma or delirium. Hiccup and subnorma temperature are mentioned as late features. The tim of onset of symptoms depends on the concentration o arsine and to a slight extent on the previous condition o the patient. The average time from exposure to onse of symptoms is 3–6 hours, with extremes of a few minutes and 24 hours.

Other workers broadly agree with these findings, and it seems that the outstanding features are severe constitutional upset, bloody urine, jaundice, and rapidly developing anæmia. Pyrexia has been reported in some cases. The sequence of onset of the features has been recorded as bloody urine in 4–6 hours, jaundice in 16–24 hours (Hunter 1943, Hawlick and Ley 1946), and anæmia on the third day (Hunter 1943) after exposure. Death may take place with extreme rapidity, or the patient may linger for 30 days (Glaister 1908, 1913), but death usually occurs between the third and seventh days (Glaister 1908, 1913). The case-mortality is about 30% (Glaister 1908, 1913). In survivors complete recovery seems to be the rule. Cases of chronic arsine poisoning have been described (Dudley 1919, Bulmer et al. 1940); these presented an additional feature in the form of subjective phenomena which were attributed to peripheral neuritis.

PATHOLOGY

Pathological findings were described by Glaister (1908, 1913) in nineteen fatal cases. The salient features are an enlarged liver, which is sometimes bile-stained; enlarged dark kidneys with prominent glomeruli; a dark, congested, friable, and sometimes enlarged spleen; and hyperæmia of the stomach and intestines, which sometimes show submucous hæmorrhages.

Histologically the hepatic cells show cloudy swelling and fatty degeneration; the renal glomeruli show detachment and proliferative swelling of the epithelial lining of Bowman's capsule; the renal tubules are in a state of desquamative inflammation, containing breaking-down corpuscles and hyaline, bloody, and fatty casts; and brown pigmentation is present in the hepatic, renal, intestinal, and cardiac cells. Other descriptions are substantially the same, except that the glomerular changes do not appear to be constant (Smith and Rardin 1939).

Examination of the blood reveals acute intravascular hæmolysis. In thirty chronic cases (Dudley 1919), 200 complete blood examinations showed a decrease in red cells with poikilocytosis, punctate basophilia, and polychromasia, but no increase in fragility. The white cells showed little change, though there was a small absolute increase in lymphocytes. The blood non-protein nitrogen is raised, sometimes to very high levels.

The urinary findings include hæmoglobinuria, methæmoglobinuria, and excess urobilin. The urinary deposit contains red-cell debris, granular material, and hyaline, bloody, and fatty casts. Urinary arsenic estimations (as As_2O_3) show very high values in the acute phase (Wignall 1920).

Hair and Nails.—The arsenic content of hair and nails has been determined in chronic cases (Dudley 1919) and significant values found; but in view of the possibility of contamination by arsenical dust in many of these cases caution should be used in interpreting the results.

CASE-RECORD

A male chemical-factory worker, aged 37, became ill on Nov. 12, 1948. His health had been normal, except that in July, 1948, he had developed a left facial palsy, and a mild paresis remained at the time of his admission. The onset of this palsy had antedated any contact with chemical mixtures. He had been employed in various capacities in the mixing department of the factory for 2 months. This work had involved the handling of arsenical powders, but full protective precautions had been observed.

On the morning of Nov. 12 he was working with a mixing machine. A mixture for preserving wall-boards, containing powdered white arsenic (As_2O_3), was made in the machine. After this the machine was swept but not washed out, and it was then used to mix a soot-removing compound consisting of common salt 440 lb., borax 22 lb., ammonium sulphate 22 lb., powdered sulphur 22 lb., oxalic acid 33 lb., and zinc dust 44 lb. The machine was started at about 8.30 A.M. and operated for about 45 min. During most of this time the lid was off. The patient alone was exposed to fumes from the mixture. He was not wearing a mask. At midday he began to have mild colicky upper abdominal pain. At 2 P.M. he passed bloody urine and at about the same time felt cold, started to shiver, and had a slight epistaxis. Next day he began to vomit, and he continued to eject all food for 48 hours. On the 14th he was jaundiced, and this steadily deepened. On Nov. 15 his liver edge was palpable and tender, his urine was less bloody but contained albumin, and his blood-urea level was 95 mg. per 100 ml. On Nov. 12–15 his temperature rose each evening to about 100·4°F. He was transferred to University College Hospital on Nov. 16.

On admission his general condition was fair; he was active and of normal mentality; he was obviously anæmic and showed warm cyanosis of his nose, lobes of ears, and finger-tips. He was considerably jaundiced, the resultant skin colour being a pale dusky yellow. Temperature 99·6°F, pulse-rate 86, respirations 20 per min. Systematic examination revealed only a few rhonchi at his lung bases, slight hyperkeratosis of the skin over his knees, and the facial palsy noted above. His liver was no longer palpable or tender. There was no evidence of hæmorrhage into his skin or mucosæ. His urine contained a trace of albumin, occasional pus cells, 1 red cell per $^1/_6$ in. field, very occasional granular casts, no bile, excess urobilin, and no hæmoglobin.

Blood Examination.—Hb 40% (Haldane); the red cells showed hypochromia and moderate anisocytosis; white-cell count 7200 per c.mm. (polymorphs 72%, lymphocytes 16%, monocytes 11·5%, eosinophils 0·5%); reticulocyte-count 5 per 100 red cells.

Treatment and Progress.—The patient was given a drip transfusion of two bottles of packed red cells. He subsequently made an uninterrupted recovery. His liver edge was palpable 1 in. below his costal margin on Nov. 19 but it was not tender; it receded to the costal margin in a week. His urinary output was satisfactory throughout. Further treatment consisted of the administration of ferrous sulphate gr. 12 daily by mouth. The Hb rose steadily to 88% on Dec. 7. Reticulocytes remained at 5% until Nov. 26 and had dropped to 0·4% on Dec. 7. On Nov. 17 the van den Bergh test showed a positive direct reaction and an indirect reaction of 2·0 units. On Nov. 18 examination of the blood-serum showed methæmalbumin (Fairley 1941) and a pigment behaving like sulphæmoglobin but with absorption-spectrum (α line) at 624·5 mμ in place of the expected 620 mμ. It was considered that this might be due to interference by methæmalbumin. On the same day the urine contained no excess of porphyrins. The blood-urea level was 48 mg. per 100 ml. on Nov. 18, 36 mg. on the 26th, and 42 mg. on Dec. 7. On Dec. 2 the urine contained no albumin, occasional pus cells, 1 red cell per $^1/_6$ in. field, and no casts.

Renal-function Tests.—On Dec. 6 the concentration test showed a maximum specific gravity of 1·020, and the dilution test showed a minimum specific gravity of 1·002. On the 7th the Van Slyke urea-concentration test showed a standard clearance of 60% and a maximum clearance of 70%.

Liver-function Tests.—On Nov. 29 colloidal-red, cephalin-cholesterol, and thymol-turbidity tests were normal. On Dec. 1 the hippuric-acid excretion test was normal.

Arsenic Content.—On Nov. 18 blood was taken for estimation of its arsenic content, which was found to be 0·95 parts per million.

Follow-up.—When the patient attended for examination on March 28, 1949, he was feeling very well and doing a full day's work, with overtime. His blood-pressure was 144/80 mm. Hg, and blood-urea 27 mg. per 100 ml. His urine contained no albumin, cells, or casts. A blood-count showed red cells 4,800,000; Hb 96%. The colloidal-red, cephalin-cholesterol, and thymol-turbidity liver-function tests were normal.

FURTHER CHEMICAL INVESTIGATIONS

Tests were carried out by Prof. C. Rimington, using chemicals supplied by the patient's firm, in the British Pharmacopœia apparatus for the detection and determination of arsenic by the yellow stain produced on mercuric-chloride paper. The chemicals were mixed in the proportions noted above. A control experiment without addition of arsenious oxide revealed the release of a trace of arsine. The experiment was then repeated, 0·1 mg. of arsenious oxide being mixed in the solid state with the other ingredients. The stain after an hour corresponded to about 10–15% conversion of As_2O_3 into arsine. The conclusion seems warranted that, during the mixing on the day of the accident, the residue of arsenious oxide in the mixing machine was partially reduced to arsine by the hydrogen released when oxalic acid reacted with zinc dust.

DISCUSSION

Differential Diagnosis

Conditions which may be confused with arsine poisoning are paroxysmal hæmoglobinuria, Weil's disease, potassium chlorate poisoning, pyrogallic acid poisoning, and blackwater fever (Glaister 1908, 1913). In industrial poisoning, mixtures of gases may be present (Hake 1910) and may confuse the diagnosis in the early phases. The history and clinical features in the present case clearly indicated arsine poisoning, and the laboratory findings were in agreement with this diagnosis.

Concentration of Arsine

It was impossible to estimate the concentration of arsine to which the patient was exposed. It is said that concentrations of 3–10 parts per million in air will produce slight symptoms after several hours' exposure, and that 16–60 parts per million will be dangerous after half to one hour's exposure. A concentration of 250 parts per million may be fatal after half an hour's exposure (McNally 1937, Henderson and Haggard 1943).

Mode of Action

Several workers have tried to elucidate the mode of action of arsine. Naunyn (1868) showed that lysis of red cells in vitro by arsine occurred only if oxygen was present. Subsequent workers have confirmed his findings. Hæmoglobin is the only constituent of blood that will react vigorously with arsine, and arsine is fixed in blood in a non-volatile form (Meissner 1913). This fixation of arsine is ascribed to oxidation to arsenious acid and arsenites or arsenic acid, or to the formation of a complex compound (Meissner 1913, Graham et al. 1946, Levvy 1946, 1947). The fixed arsenic is largely confined to the erythrocytes up to the time of hæmolysis (Thauer 1934, Graham et al. 1946).

Of the arsenic in the blood of rabbits poisoned with arsine 50–100% has been shown to be non-dialysable. This non-dialysable fraction seems to exist in two forms, the major of which behaves as arsenite after treatment of the blood with ferricyanide. The dialysable fraction seems to be present as an arsenite (Graham et al. 1946).

In the belief that arsine is probably converted to arsenite in the red cells, the effect of intraperitoneal arsine and arsenites has been investigated, and the toxicity of arsine has been found to be much greater than that of arsenites. As an explanation of this effect it has been suggested that some arsine remains free and has a direct action on vital organs, or alternatively that a proportion forms an unknown compound, probably a trivalent intermediate between arsine and arsenite, and that this has a similar effect (Levvy 1946, 1947, Hughes and Levvy 1947).

There seems to be no record of observations on the rate of removal of arsenic compounds from the blood after arsine poisoning in man. Most persons are exposed in addition to arsenic in other forms, and this would vitiate results.

Treatment

Rest is important; sudden death has been attributed to early activity in convalescence (Glaister 1908). Blood-transfusion is often necessary to replace the hæmolysed cells (Glaister 1913, Bulmer et al. 1940, Hawlick and Ley 1946).

The urine should be kept alkaline to reduce the effects of the hæmolytic products in the renal tubules (Wilson and Mangun 1943).

The value of 2–3, dimercapto-propanol (dimercaprol or BAL) in experimental arsine poisoning has been investigated by Kensler et al. (1946). It has a protective effect, but this diminishes so rapidly with the lapse of time after exposure that it is of little therapeutic value. A related compound, 2–3, dimercaptopropyl-ethyl ether, is more effective in protecting animals (Kensler et al. 1946, Riker 1946) but suffers from the same defect and has no effect on mortality when administered more than 5–6 hours after exposure. This substance has been noted to damage the central nervous system in animals when given intravenously but not when given subcutaneously. There is no record of its use in arsine poisoning in man; but it has been given subcutaneously to normal persons in doses comparable with those used successfully in animals, and no ill effects have been noted. It has been postulated that the protective action of these compounds depends on their reaction with oxidation products of arsine, probably arsenites; but this has not been proved (Kensler et al. 1946).

The value of dimercaprol and its derivative is cle
very limited. The interval since exposure con
indicated their use in the present case. One case of ar
poisoning treated with dimercaprol within 24 hours
been reported (Garlick 1949). The patient recove
but (as Garlick states) this may well have been beca
he had been exposed to a sublethal dose.

SUMMARY

A case of industrial arsine poisoning is described.
clinical and laboratory findings were typical. The pati
assisted by transfusion therapy, made an uninterrup
recovery and remained well 4½ months later. Spec
therapy was considered to be contra-indicated.

The ætiological, clinical, pathological, and therapeu
aspects of arsine poisoning are discussed.

We wish to thank Dr. J. C. Hawksley, at whose suggest
this case is published; Professor Rimington, for the investi
tion of the chemical pathology; and Dr. F. H. King, H.
Medical Inspector of Factories, for information about t
industrial aspects of the history.

SEVERE URTICARIA COMPLICATING STREPTOMYCIN THERAPY

DAVID C. LINDARS
M.B. Manc.
CAPTAIN, R.A.M.C., MILITARY WING, BAGULEY E.M.S. HOSPIT
MANCHESTER

SKIN eruptions in the course of streptomycin treatme
are common, but usually they are transient and n
considered to be an indication to discontinue treatme
In the first controlled investigations of streptomycin
clinical use in America skin reactions occurred in 30 out
706 cases treated (de Bakey and Pulaski 1946).
none of these was it found necessary to stop the tre
ment, and the conclusion of these workers was th
"vestibular disturbance is the only complicati
presently considered to be an indication for terminati
of drug therapy." The Medical Research Council co
mittee (1948), reviewing 52 cases of pulmonary tuberc
losis treated with streptomycin, stated that "tox
effects of streptomycin were observed in many patient
but in no single case did they necessitate cessation
treatment." The same conclusion was reached by t
Ministry of Health Standing Advisory Committee
Tuberculosis (1949), which asserted: "Sensitisati
reactions, such as skin erupti

stages of treatment are usually relieved by anti-histamine drugs."

Where streptomycin has been studied specifically for its toxic effects skin eruptions have been considered to be sufficiently mild for the drug to be continued in spite of them or, if more severe, to be resumed after a short interruption. Farrington et al. (1947) studied the toxic effects of a preparation of streptomycin which was at least 95% pure. In 2 of 14 cases extensive rash and fever developed, necessitating stopping the streptomycin, but in both cases it was resumed without ill effect some weeks later. Steiner and Fishburn (1947) studied 6 cases of skin eruption occurring in 33 cases treated with streptomycin, in no case was it necessary to interrupt treatment for more than a week.

A note of warning, however, had been sounded by the committee of chemotherapeutics of the National Research Council (1946). In this investigation 49 of 1000 patients treated with streptomycin developed skin eruptions, which were more common and more severe in patients receiving more than 1 g. of streptomycin daily. In nearly all the cases streptomycin was continued, but in a few cases it had to be withheld. The report recommended: "In most instances it is well to stop the streptomycin if a skin eruption appears; certainly the dose should be reduced, and if treatment is continued it should be done with care and caution." Earlier workers had noted severe reactions, and Heilman et al. (1945) advised: "Although administration of streptomycin may be continued in the presence of these cutaneous eruptions, it is exceedingly important to remember that severe dermatitis may result." The Veterans Administration (1947) found that a maculopapular rash appeared in 41 of their 223 patients, and that "the pruritus was usually easily controlled with 'Benadryl' and the eruption disappeared with continued treatment. In three instances however, a severe exfoliative dermatitis developed, and in only one of these could therapy be resumed subsequently." Major E. Woolf, R.A.M.C. (personal communication), mentions a case under his care in which extensive urticaria occurred and streptomycin had to be withheld. The "sprue-like mouth and swelling of the lips" described by Thevathasan (1949) may also be a sensitisation phenomenon.

In the case described below the skin eruption was so severe that the streptomycin had to be discontinued.

CASE-RECORD

A National Serviceman, aged 18½, was admitted to the military wing of this hospital on April 21, 1949. He had been transferred from another military hospital, where treatment with streptomycin had been begun on April 4 for bilateral pulmonary tuberculosis with recent spread and tuberculous laryngitis. No symptoms had been noted which could be attributed to streptomycin toxicity. On admission he weighed 8 st. 4 lb. and his temperature range was 98–99°F. It was decided to continue streptomycin 0·5 g. twice daily, with the patient at strict rest in bed.

Skin Eruption.—On April 25 an itchy papular rash appeared on both forearms and legs, coming up after each injection of streptomycin. Benadryl 50 mg. was given before each injection, and by this means the rash was kept under control for a week. On May 3, however, it reappeared, and this time affected the chest and back also. There was a rise in temperature to 100°F. Streptomycin was continued, with benadryl, but during the next two days the rash slowly spread and the constitutional upset became more severe. On May 5 the rash covered the whole trunk and limbs and was now more blotchy. The face was red, œdematous, and peeling, and there was œdema of the external genitalia. Constitutional disturbance was severe, with drowsiness and photophobia, and the temperature had risen to 103–104°F. The white-cell count was 22,150 per c.mm., with an absolute lymphocytosis (polymorphs 27·5%, lymphocytes 69·5%, eosinophils 0·5%, monocytes 2·5%). Streptomycin was discontinued, and 50 mg. of 'Phenergan' at night was substituted for the benadryl. Next day the dose of phenergan was increased to 100 mg. twice daily, because the eruption had not improved when the streptomycin was stopped. The rash and general condition continued to worsen for the next two days.

On May 8 the rash had slightly improved, though the pyrexia continued. The face was still grossly swollen and was beginning to break down, with cracking about the mouth. There was a serous discharge from the scalp. The white-cell count now showed a polymorph leucocytosis superimposed on the lymphocytosis: white cells 43,750 per c.mm. (polymorphs 43·0%, lymphocytes 48·5%, eosinophils 4·5%, monocytes 4·5%): so penicillin 200,000 units eight-hourly was started.

Next day there was considerable improvement, with reduction in pyrexia to 99–100°F, and corresponding improvement in general condition. The rash had started to desquamate, and the face was much less swollen, though the infection about the mouth and on the scalp was unchanged. Phenergan was discontinued.

A slow recovery now took place, complicated, however, by the frequent appearance of septic spots in the skin, the nutrition of which had been much impaired. Additional complications were conjunctivitis and a small deep venous thrombosis in the left calf. The white-cell count at first reverted to an absolute lymphocytosis, and thereafter slowly returned to normal.

Intradermal testing was done two months after the eruption had cleared with a solution of streptomycin containing 50 µg. (50 units, Waksmann) in 1 ml. of sterile distilled water; 0·1 ml. was injected intradermally into the skin on the forearm, and as a control the same quantity of distilled water was injected into the opposite forearm. Reddening of the injection site was noted after about three hours, and reached a maximum after twelve hours, when it covered an area the size of a sixpence, thereafter fading slowly. No reaction occurred in the control site.

PARTICULARS OF STREPTOMYCIN USED

The preparation of streptomycin used at this hospital was the calcium chloride complex (Glaxo), and inquiry showed that the same had been used for this patient at the military hospital from which he was transferred. In neither case are records of batch numbers available, but it seems unlikely that the same batch would be in use at both hospitals, which are far apart. The dose at both hospitals was 1 g. daily in divided doses at twelve-hour intervals. The total dose was 32 g. The first sign of sensitisation appeared on the twenty-second day of treatment (fourth day at this hospital), and the drug was stopped on the thirty-second day.

DISCUSSION

Steiner and Fishburn (1947), from a consideration of 6 cases, regarded skin eruptions in the course of streptomycin therapy as allergic. They found a history of hay-fever in the patient or a near relation in 3 of their cases, and in 5 cases the symptoms had come on within the first ten days of treatment; in the 6th case the onset was on the twenty-sixth day. Eosinophilia was usually present and tended to persist with continued treatment, after the rash had disappeared, until the end of the course. If the streptomycin was withheld, the rash improved by next day. Other investigations have produced similar findings.

Pyrexia has often been noted in patients with skin reactions, though it was not a feature of the cases reported by Steiner and Fishburn. These workers observed œdema of the eyelids and lips in the patient whose reaction developed on the twenty-sixth day, but œdema does not seem to be very common.

In the present case the patient had been under treatment for twenty-two days before any rash was observed, but this may be because he had been transferred to a different hospital on the eighteenth day of treatment. There was no break in the streptomycin treatment, but a different batch was probably used. If so, the reaction could be regarded as developing on the fourth day of treatment; but, since Farrington et al. (1947) indicate that the causal factor is the streptomycin and not impurities, the onset seems to have been abnormally delayed, as in the case described by Steiner and Fishburn.

An absolute lymphocytosis is very unusual, and does not seem to have been noted previously as a reaction to streptomycin. No other cause for this blood picture was found, however, and it is significant that the lymphocytes slowly returned to normal during the patient's recovery.

The anti-histamine drugs at first controlled the rash adequately, and the use of benadryl enabled treatment to be continued for a week. When the rash reappeared, however, these drugs were of no value, and the eruption spread rapidly, even after streptomycin had been discontinued. No history of hay-fever in either the patient or his relations was obtained.

The response to stopping streptomycin therefore was not so immediate as is usually expected in a sensitisation reaction. The lack of improvement on stopping the streptomycin and increasing the dosage of phenergan may possibly have been due to streptomycin being held back by the œdema, when normally it would have been eliminated from the body.

The result of intradermal testing was not so definite as had been anticipated. This may have been because the solution of streptomycin used was very dilute—ten times more dilute than that used in the intradermal test described by Crofton and Foreman (1948). The long interval between the onset of the reaction and the test is also a factor, since most workers have found decreasing reaction to a test dose of streptomycin the longer the interval since the original reaction.

SUMMARY

A rash developing on the twenty-second day of streptomycin treatment was at first easily controlled with benadryl.

Streptomycin therapy was continued, as recommended by several workers, but it had subsequently to be stopped because of the severity of the skin reaction and the serious constitutional disturbance. Thereafter recovery was slow.

The tendency to regard skin reactions to streptomycin as mild and transient and easily controlled with anti-histamine drugs should be modified. They should always be regarded as potentially dangerous, and if the treatment is continued great caution should be observed.

My thanks are due to the Director-General, Army Medical Services, for permission to publish this case, and to Dr. H. G. Trayer, medical superintendent, Baguley Sanatorium, for much valuable advice and criticism.

"... What can the medical school do to add new dimensions to medicine ? As a minimum, it can give students opportunity to study people throughout the medical course, in a natural setting, long enough at a time so that current impressions fall into perspective, and from every relevant point of view. ... At some schools the first step has been to bring a psychiatric component into the clinical departments, particularly medicine and pediatrics. This is done not primarily for the sake of better handling of mental disease, but to take advantage of the psychiatrist's skill in getting and evaluating the kind of information about patients that eludes conventional diagnostic methods, and in putting this information to good therapeutic use."—*Annual report of the Commonwealth Fund*, 1949.

EXFOLIATIVE DERMATITIS COMPLICATING STREPTOMYCIN THERAPY

W. C. HARRIS

REGISTRAR

R. V. WALLE
M.B. Camb.
HOUSE-PHYSICI

TUBERCULOSIS UNIT, WEST MIDDLESEX HOSPITA
ISLEWORTH

THE toxic effects of streptomycin are classifi Farringdon et al. (1947) into four main groups: mine reactions, anaphylactic reactions, nerve le and renal lesions. Skin reactions to streptomyci anaphylactic (McDermott 1947) and form, with feve eosinophilia, a triad whose members may occur tog or separately.

According to McDermott (1947) 5% of patients u going streptomycin therapy develop skin eruptio the second or third week. The rash is variabl distribution and character, is identical with that pro by other chemotherapeutic agents, is usually pruritic may go on to a superficial scaling. Bunn (1948), re ing 650 cases of various infections treated with str mycin for the Veterans Administration, states streptomycin may give rise to anaphylactic reac of which exfoliative dermatitis is the most impo though rare, but he does not mention its incid The report of the Council on Pharmacy and Chem (1947) gives more information about skin reactio streptomycin :

> "A pruritic, erythematous, maculopapular skin eru at first localised, appeared in a considerable percenta cases after about ten days of treatment. The pruritus usually relieved by 'Benadryl.' Treatment need no stopped because of the rash unless it develops in generalised exfoliative dermatitis . . . 7 such cases (0 occurred in the present series."

Heilman et al. (1945), reporting on 40 pati observed the development of dermatitis and sugge that, if streptomycin therapy is continued, a se condition may develop, but no specific mention is m of exfoliation. The only further mention of exfolia is by Albertal et al. (1948), who, reporting on 50 pati treated with streptomycin in private practice, men it as a complication but do not indicate its incide Three further papers which discuss skin reactions streptomycin—the National Research Council (1 report on 1000 patients and the articles of Steiner Fishburn (1947) and of Davies et al. (1948) do specifically mention exfoliation.

From all the published reports it seems that cutan reactions to streptomycin (apart from contact dermat though widely noted, are uncommon, and that exf tion is extremely rare. Neither dosage nor purity se to be important and McDermott (1947) noted the s sort of reaction in patients receiving highly pur streptomycin.

We have treated 60 tuberculous patients with stre mycin and have observed skin reactions in 3 (5%) of th In the first case a mild pruritic eruption appeared on extensor surfaces of the arms and thighs; it respon favourably to benadryl, and streptomycin therapy continued. In the second case there was a pleomorp and more generalised rash consisting of erythemat and maculopapular elements; it was pruritic a distressing to the patient and did not respond 'Antistin.' This developed on the eighth day of w was to have been a ten-day course of 2 g. daily, a because of the distress it caused, streptomycin thera was abandoned on the ninth day. Next day all infla mation and symptoms had subsided and by the eleven day the skin lesion had completely disappeared. T third case is reported below.

CASE-RECORD

A married woman, aged 45, was diagnosed as having pulmonary tuberculosis in January, 1941. At that time she had an infiltrating lesion in the upper zone of the right lung. She responded well to rest and graded activities, and in April, 1943, was regarded as quiescent with a fibrotic lesion in the right upper zone. She remained well and undertook full household activities, and when seen at the chest clinic in January, 1949, she was told to report again a year later.

In June she developed an acute febrile illness with chest symptoms, and her own doctor treated her for pneumonia with sulphadimidine ('Sulphamezathine'), the exact dosage of which we have not ascertained. During this course the patient developed a rash which she described as "just like measles." She did not respond to chemotherapy and was seen by Dr. Hugh Climie, who arranged for her admission to the West Middlesex Hospital on July 26.

On admission her general condition was very poor; she had dyspnœa at rest and mild cyanosis. Her temperature was swinging to 104°F, and she had a troublesome cough with purulent sputum. Radiography revealed an extensive spread of disease throughout the right lung, and the sputum contained tubercle bacilli. Blood-count: Hb 70%, red cells 3,500,000 and white cells 17,200 per c.mm. (polymorphs 91%, lymphocytes 8%, monocytes 1%). Streptomycin was started next day, 1 g. being given daily in a single intramuscular injection. By the third day there was slight improvement in the patient's general condition, and her temperature looked as if it might be settling (fig. 1). All seemed well until the ninth day, when her temperature rose again to 103°F and there was a further deterioration in her general condition.

Skin Reaction.—On the ninth day the first sign of skin reaction appeared as a dull red erythematous, but not pruritic, eruption on the upper abdomen. Next day the eruption had become a maculopapular rash extending to the dorsal surfaces of the arms. There was still no pruritis, and the patient was in no way troubled by the rash. At this stage it was decided that, in the absence of symptoms and in view of the severity of the tuberculosis, streptomycin therapy should be continued. It was thought that little benefit would be gained by giving anti-histamine drugs, so these were withheld.

The position remained much the same until the thirteenth day, when the patient complained of a sore mouth and sore eyes and was found to have a mild stomatitis, with cheilosis and conjunctivitis. Swabs were taken from both sites, but no significant organisms were grown. At this stage benadryl 50 mg. t.d.s. was started.

On the fifteenth day vesiculation was noted in the elbow region and the maculopapular eruption had become more general. On the appearance of vesiculation the streptomycin was stopped and the dosage of benadryl increased to 100 mg. t.d.s. 'Benerva' (vitamin B_1) 2 mg. b.d. was also given. With the development of vesiculation the stomatitis became severe, and the patient could take nothing but fluids.

The day after the streptomycin had been stopped the patient's temperature fell dramatically, but she remained extremely ill, and her skin condition progressed through the stages of vesiculation to complete exfoliation, which reached its height on the twentieth day. At this stage antistin was substituted for benadryl, the patient was also given one ampoule of 'Amytox' intramuscularly daily for seven days, 100 mg. of vitamin C daily, and 6 minims of 'Adexolin' (vitamin A 12,000 i.u., vitamin D 2000 i.u.) daily. From then on the condition subsided rapidly. Photographs (fig. 2) taken on the twenty-third day show the degree of denudation which took place. A blood-count at this stage revealed a complete absence of eosinophils—white cells 7600 per c.mm. (polymorphs 72%, lymphocytes 28%).

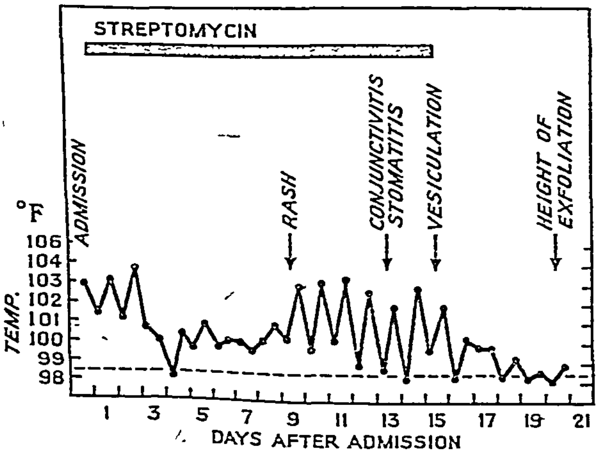

Fig. 1.—Chart showing onset and course of reaction to streptomycin.

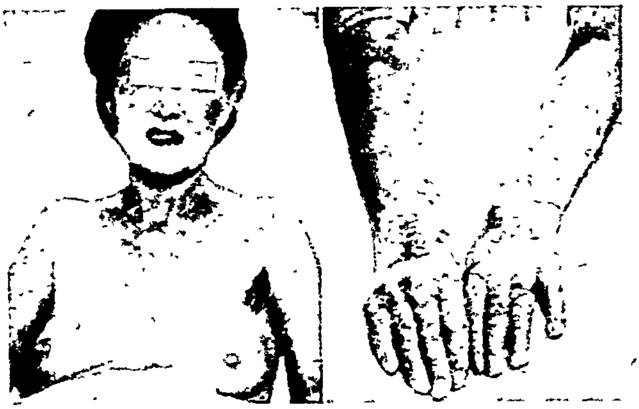

Fig. 2.—Exfoliation on twenty-third day from start of streptomycin treatment.

By the twenty-seventh day the inflammation had subsided completely, and desquamation only was present. The stomatitis and conjunctivitis had also cleared completely, and a full diet could be taken. The patient's general condition began to improve from the twenty-third day onwards, and her temperature remained at a lower level. Radiography on the thirtieth day revealed considerable clearing of the acute exudative element of the tuberculous lesion. By the thirty-fourth day the skin was clear, except for some mottled pigmentation on the abdomen.

DISCUSSION

As already stated, at the onset of the rash we felt justified in continuing with the streptomycin because of the absence of discomfort and the severity of the tuberculosis. But we are not so sure that it was justifiable to continue streptomycin therapy after the development of the stomatitis. At that time we did not realise that stomatitis was a known toxic effect. We have since found a report (Beham and Perr 1948) of three cases, two of which were associated with dermatitis, one of which later desquamated. Beham and Perr regard stomatitis as a severe anaphylactic reaction and advocate immediate cessation of the streptomycin. Perhaps we might have halted the exfoliation if we had withheld streptomycin at this stage.

A feature of the present case was the speed with which the skin cleared when streptomycin was withheld, though at its height this was a severe example of exfoliative dermatitis, comparable with that which may follow gold and arsenic therapy.

The fact that we have been unable to find any report of a fatal case of skin reaction to streptomycin in no way detracts from the seriousness of the condition. Obviously every effort must be made to avoid it; yet one can only be sure of doing so by withholding streptomycin at the first sign of a rash; this would not usually seem justifiable. A small risk is undoubtedly being taken every time it is decided to continue giving streptomycin once a skin reaction has developed, and in each case this risk must be balanced against the risk of stopping the treatment.

SUMMARY

Exfoliative dermatitis as a reaction to intramuscular streptomycin seems to be extremely rare; the only published report of its incidence gives the figure of 0·8% in 1000 cases.

In the present series 3 patients out of 60 (5%) treated with streptomycin for tuberculosis developed skin reactions, one of which went on to exfoliation and was associated with stomatitis and conjunctivitis.

The hazards of continuing streptomycin therapy in the face of a skin reaction are discussed, and it is suggested that these hazards must be considered in their relation to the disease for which streptomycin is indicated.

We wish to thank Dr. Climie, under whose care this patient was admitted for treatment, for permission to publish this report, and for his encouragement and advice; Dr. J. Morgan for his advice and help on treatment from the dermatological point of view; and the nurses, who did so much to help the patient tide over a very trying time.

ACUTE DIVERTICULITIS OF THE CÆCUM AND ASCENDING COLON

RICHARD E. SHAW
Ch.M. Leeds, F.R.C.S.
CHIEF ASSISTANT IN SURGERY

J. SIEGLER
M.B. Lond.
LATE HOUSE-SURGEON

WEST MIDDLESEX HOSPITAL, ISLEWORTH

DIVERTICULA of the right side of the colon were previously regarded as rare compared with those of the left side. Bennett-Jones (1937) could find only 20 cases of acute diverticulitis of the cæcum published in this country. Since then, however, this condition has aroused much interest, and numerous workers have reported further examples and discussed their management. Anderson (1947) collected 91 published cases and added 8 from the records of the Mayo Clinic, and additional cases have been reported by Fairbank and Rob (1947), Perazo (1947), and Henry (1949). The increased interest in this condition may be attributed in part to the realisation that it is not so uncommon as was at one time thought and in part to an appreciation that it is an important surgical lesion. Not only is a preoperative diagnosis almost impossible but the surgeon may not recognise the acute diverticulitis at operation, and, confusing it with a perforating carcinoma of the cæcum, may perform an unnecessarily extensive resection.

A word is needed to clarify the nomenclature. Diverticula of the right side of the colon are found most often in the cæcum, and inflammation of these diverticula is usually termed acute diverticulitis of the cæcum. In many of the reported cases, however, the lesion has been above the ileocæcal valve; for the sake of accuracy, therefore, such lesions should be called diverticula of the ascending colon, though since they are low down, near the cæcum, the distinction is not important, so long as the point is borne in mind.

CASE-RECORD

A woman, aged 42, was admitted to the West Middlesex Hospital on Feb. 28, 1949, with forty-eight hours' history of pain in the right iliac fossa. The pain was fairly severe, did not radiate or change position, and was aggravated by movement. She experienced nausea without vomiting, and there had been diarrhœa since the onset, especially during the first twenty-four hours. She complained of slight scalding on micturition. Her menses were regular, with a rhythm of 5-6/28 days, but for two years she had had pain in the mid-abdomen for a week before the onset of menstruation. On the whole her symptoms appeared to be abating on admission. For some six weeks she had been away from work with bronchitis, and had only returned to it five days before admission. There was also a history of two attacks of "gastro-enteritis," each lasting two or three days, one in September, 1948, and the other in February, 1949, characterised by abdominal pain and diarrhœa. She had had rheumatic fever in childhood.

Physical Signs.—Temperature 98·2°F, pulse-rate 68, respiration 20 per min. The tongue was moist and clean. The abdomen moved fairly well on respiration, and there were tenderness and muscle guarding in the right iliac fossa, where it was thought that an indefinite mass could be felt, though opinion was divided on this point. Rectal examination was negative, and no abnormal signs were found in the cardiovascular and respiratory systems. The provisional diagnosis was acute appendicitis.

Operation.—The abdomen was explored through a lower right paramedian incision. The appendix appeared normal, but an inflammatory mass about an inch in diameter was found on the posteromedial wall of the ascending colon about half an inch above the ileocæcal junction. The peritoneum over the mass was incised and gently dissected free, revealing an inflamed diverticulum of the colon about half an inch deep. Its base was clamped, the diverticulum removed, and the stump ligated and oversewn. The appendix was removed and the abdomen closed.

Progress.—Convalescence was uneventful, and the patient was discharged home on March 15, 1949. A barium enema on April 19 showed no evidence of diverticula in any part of the colon.

Pathological Report (Dr. A. C. Counsel).—The specimen was a hemispherical diverticulum, ½ inch in circumference, and ½ inch long, lined with normal colonic mucosa which showed well-marked capillary hyperæmia. The interstitial tissue of the mucosa contained many lymphocytes and plasma cells and very few polymorphs. Beneath the mucosa was a well-marked layer of muscularis mucosæ which was penetrated by a few large lymph follicles. The muscularis was represented by a small single bundle of plain muscle. Otherwise this coat was completely deficient. The extramuscular fibrous tissue showed fairly recent hæmorrhages, with young fibroblasts and new capillaries, the result of organisation. This layer showed foci of sparse infiltration with lymphocytes and a few eosinophils.

DISCUSSION

Though usually described as solitary, diverticula of the cæcum are occasionally multiple. There are two varieties: (1) a true congenital type, with mucous, muscular, and serous layers in its wall; and (2) a false type without any muscular coat. The distinction may be significant in that the false variety, possessing no muscular coat, is less likely to be capable of ejecting a fæcolith or other obstructing agent, and may therefore be more liable to inflammation. Cæcal diverticula have usually been regarded as pulsion diverticula in the sense that they are related to a raised intracolonic pressure, but a few instances have been described of the traction variety, where the diverticulum has been produced by the contraction of adherent fibrous tissue—e.g., in association with calcified mesenteric glands (Dorling 1945). Fairbank and Rob (1947) suggest that the false variety may be a sequel of simple ulceration.

The average age of patients with this condition was 39·1 years in Anderson's (1947) collected series, and the sex-distribution was equal. In these two respects there is an interesting difference from diverticulitis of the sigmoid, which is found in an older age-group and is twice as common in men as in women.

A diverticulum of the cæcum, like the appendix, is liable to undergo inflammation, especially if its mouth is obstructed by a fæcolith, and the pathological course of the diverticulitis bears some resemblance to that of acute appendicitis. Resolution, local or general peritonitis, an abscess, perforation, or a fistula may result. General peritonitis is, however, rare, and the usual finding is a localised inflammatory mass round the cæcum. One instance of torsion of a diverticulum has been recorded (Thomsen 1935).

Diagnosis.—As in the present case, the preoperative diagnosis has most often been acute appendicitis. This was true in 84% of Anderson's (1947) collected cases. Indeed, as more than one writer has pointed out, there seems to be no way in which the two conditions can be distinguished clinically. A barium enema is contraindicated in acute appendicitis, and in any event the investigation would be of little value since the mouth of the diverticulum is often blocked by a fæcolith or by inflammation. Acute diverticulitis should be borne in mind as a possible diagnosis when a patient presents the clinical picture of acute appendicitis but the appendix has previously been removed. Some cases which receive conservative treatment as appendix abscesses, and undergo resolution, may really be examples of acute diverticulitis of the cæcum. For this reason, when delayed appendicectomy is performed on this type of case, the cæcum should be examined for diverticula, especially if the appendix does not appear grossly diseased. Even at operation the diagnosis may be in doubt and the condition not be recognised. In nearly every published case a mass related to the cæcum has been found on laparotomy, and a right hemicolectomy has often been done by the surgeon in the mistaken belief that he was dealing with a malignant condition of the cæcum. That this error should have been made so many times is not surprising, since carcinoma of the cæcum is much more common than diverticulitis; but, if diverticulitis is borne in mind, and if the mass is carefully examined to ascertain if the mouth of a diverticulum can be felt as a defect in the colonic wall an accurate diagnosis might be reached in a larger proportion of cases. In the present case the diagnosis was not made until the mass had been gently explored and dissected. The question of carcinoma did not, however, arise in this case, and exploration of the mass cannot be recommended as a routine, in view of the risk of disseminating infection or cancer cells.

Treatment.—When feasible, the correct treatment of acute diverticulitis of the cæcum is simple excision of the diverticulum, and in Anderson's (1947) 99 cases this was done 53 times, with a mortality of 4%. Where the inflammatory process is so extensive that a local excision of the diverticulum would be inadequate it has been suggested that either cæcectomy, with anastomosis of the ileum to the ascending colon, or a right hemicolectomy, should be done. These extensive procedures are, however, likely to carry a higher mortality, and Schnug (1943) has made a good case for conservative treatment. He points out that the diverticula have wide mouths opening into the colon, and discharge of their contents into the bowel and spontaneous resolution may be confidently anticipated. This reasoning appears sound, and conservative treatment is recommended when the inflammation is so extensive that simple diverticulectomy is impracticable. A delayed excision of the diverticulum may be done after an interval of about six months. Frehling (1945) suggested extraperitonealisation of the lesion so that a cæcostomy forms after forty-eight hours or so, when the diverticulum sloughs, but we feel that such a technique is unnecessarily untidy and can only rarely be indicated. When the lesion cannot be distinguished from carcinoma it should be treated as malignant and a right hemicolectomy done in one or two stages.

SUMMARY

A case of acute diverticulitis of the ascending colon is described.

The condition cannot be differentiated clinically from acute appendicitis and at operation often resembles carcinoma of the cæcum.

The correct treatment is diverticulectomy, when possible. For other cases conservative treatment is recommended, with diverticulectomy later.

We wish to thank Mr. John Scholefield, under whose care the patient was admitted, for advice and for permission to publish the case; and Dr. A. C. Counsel for the pathological report.

RELAPSE IN TYPHOID FEVER AFTER TREATMENT WITH CHLORAMPHENICOL

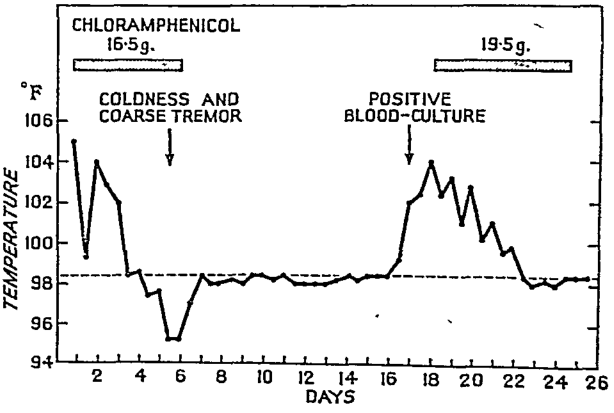
J. NIXON BRIGGS
M.B. Lond., M.R.C.P. D.C.H.
SQUADRON-LEADER, MEDICAL SPECIALIST, R.A.F.

SINCE there seems to be no definite agreement about the dosage or duration of administration of chloramphenicol ('Chloromycetin'), and in view of the few cases so far treated with it, the following case is reported.

A Dutch soldier, aged 24, was admitted with ten days' history of fever, headache, anorexia, and initial constipation followed by diarrhœa. The spleen became palpable on the third day, and on the eighth day a rose rash appeared. The patient had apparently been inoculated with T.A.B.C. vaccine a fortnight before the onset of his illness.

On admission he was extremely ill and had a temperature of 105°F. His skin was dry, and his tongue was furred centrally and clear at the edges. His abdomen was slightly distended, the spleen was readily palpable, and there were some twenty rose spots on his chest and abdomen. His blood-pressure was 80/40 mm. Hg. Other systems were normal. Despite the fact that he had been inoculated with T.A.B.C. he was thought to have typhoid fever, blood was taken for culture and for Widal reaction, and treatment with chloramphenicol was started. A loading dose of 2·5 g. was given, followed by 0·25 g. two-hourly.

Progress.—Within twenty-four hours the patient's temperature (see figure) had fallen to 99·4°F, but it rose again to 104°F, and he had a profuse epistaxis; after this second rise the temperature subsided until, sixty hours from the start of treatment, it was 98·4°F. There was a striking disappearance of subjective symptoms, and the patient became less toxic, had an appetite, and no longer complained of severe headache. On the fifth day his temperature was 95°F, he complained of feeling cold, and a coarse tremor of his hands and legs appeared; no other signs were detected in his central nervous system. In the next few hours these symptoms became more intense, so the chloramphenicol was stopped when the patient had received 16·5 g.



Temperature chart showing relapse of typhoid fever after first course of chloramphenicol.

In the present series 3 patients out of 60 (5%) treated with streptomycin for tuberculosis developed skin reactions, one of which went on to exfoliation and was associated with stomatitis and conjunctivitis.

The hazards of continuing streptomycin therapy in the face of a skin reaction are discussed, and it is suggested that these hazards must be considered in their relation to the disease for which streptomycin is indicated.

We wish to thank Dr. Climie, under whose care this patient was admitted for treatment, for permission to publish this report, and for his encouragement and advice; Dr. J. Morgan for his advice and help on treatment from the dermatological point of view; and the nurses, who did so much to help the patient tide over a very trying time.

RELAPSE IN TYPHOID FEVER AFTER TREATMENT WITH CHLORAMPHENICOL

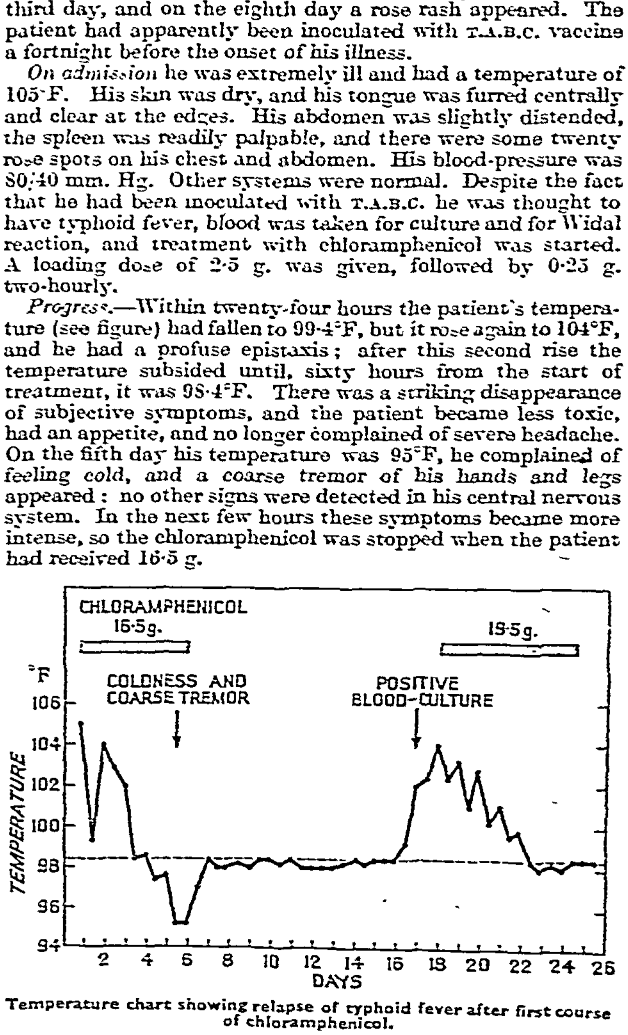
J. Nixon Briggs
M.B. Lond., M.R.C.P. D.C.H.
SQUADRON-LEADER, MEDICAL SPECIALIST, R.A.F.

SINCE there seems to be no definite agreement about the dosage or duration of administration of chloramphenicol ('Chloromycetin'), and in view of the few cases so far treated with it, the following case is reported.

A Dutch soldier, aged 24, was admitted with ten days' history of fever, headache, anorexia, and initial constipation followed by diarrhœa. The spleen became palpable on the third day, and on the eighth day a rose rash appeared. The patient had apparently been inoculated with T.A.B.C. vaccine a fortnight before the onset of his illness.

On admission he was extremely ill and had a temperature of 105°F. His skin was dry, and his tongue was furred centrally and clear at the edges. His abdomen was slightly distended, the spleen was readily palpable, and there were some twenty rose spots on his chest and abdomen. His blood-pressure was 80/40 mm. Hg. Other systems were normal. Despite the fact that he had been inoculated with T.A.B.C. he was thought to have typhoid fever, blood was taken for culture and for Widal reaction, and treatment with chloramphenicol was started. A loading dose of 2·5 g. was given, followed by 0·25 g. two-hourly.

Progress.—Within twenty-four hours the patient's temperature (see figure) had fallen to 99·4°F, but it rose again to 104°F, and he had a profuse epistaxis; after this second rise the temperature subsided until, sixty hours from the start of treatment, it was 98·4°F. There was a striking disappearance of subjective symptoms, and the patient became less toxic, had an appetite, and no longer complained of severe headache. On the fifth day his temperature was 95°F, he complained of feeling cold, and a coarse tremor of his hands and legs appeared: no other signs were detected in his central nervous system. In the next few hours these symptoms became more intense, so the chloramphenicol was stopped when the patient had received 16·5 g.



Temperature chart showing relapse of typhoid fever after first course of chloramphenicol.

Laboratory Findings.—Widal reaction: *S. typhi* O 1/480, H nil; *S. paratyphi-B* O 1/240, H 1/120; *S. paratyphi-A* and *C* nil; Vi negative. Cultures from blood, fæces, and urine proved negative.

Relapse.—After twelve hours the patient's temperature rose to 98·4°F and his tremor ceased. During the whole time his general condition was maintained and his blood-pressure ranged from 90/60 to 80/50 mm. Hg. He remained afebrile and felt well for eight days. On the eighth day his temperature rose to 102°F, and after two further days it was still 102·6–104°F. His spleen, which had previously regressed, was again palpable, and he complained of headache and nausea. A blood-culture now grew *S. typhi*, and the Widal reaction gave *S. typhi* O 1/960, Vi negative, and the other titres as before. Stool and urine cultures were still negative. On the second day of his relapse the patient passed almost pure blood per rectum. A second course of chloramphenicol was therefore started, with a loading dose of 2·5 g., followed by 0·25 g. two-hourly. The temperature fell to normal within five days, and there was no reappearance of tremor and no hypothermia. The second course of chloramphenicol amounted to 19·5 g. and lasted six and a half days. From then on the patient was afebrile, three stool and urine cultures were negative, a repeat Vi test was negative, and he was discharged after thirty-eight days in hospital.

DISCUSSION

In this case there was a dramatic response to the first course of 16·5 g. of chloramphenicol, with cessation of subjective symptoms and a normal temperature after sixty hours. Nevertheless there was a relapse with positive blood-culture eight days later; this was controlled, and the typhoid infection apparently overcome, by a further 19·5 g. of chloramphenicol given in six and a half days.

Dosage

The views on dosage vary. Messrs. Parke, Davis & Co. cite the Kuala Lumpur workers and recommend a course of 19 g. Bradley (1949), in a preliminary communication, noted that signs of resolution of typhoid fever were obvious after 8 g. Douglas (1949) reported recovery after a single course of 20 g. Of the 6 proved cases of typhoid fever surveyed by Patel et al. (1949) 3 recovered after courses of 18, 16, and 12 g., but a remission of subjective symptoms was noted early in the course of treatment.

Despite these satisfactory results on fairly small dosage Woodward et al. (1948) had 2 relapses in 10 treated cases after the patients had been afebrile for ten and sixteen days, and both cases responded to a second course. Rumball and Moore (1949), treating a chronic typhoid carrier aged 9 years, found that the stools still contained *S. typhi* after a course of 10·5 g.; after a second course of 5·25 g. the stool cultures became negative, but two days after the cessation of treatment *S. typhi* was again present in the stools. Smadel et al. (1949) recommend a course lasting nine to fourteen days; of 19 of their cases treated for this length of time none relapsed, whereas of 13 treated for eight days or less 7 relapsed. The *British Medical Journal* (1949) recommends a loading dose of 4 g. followed by 1·5 g. b.d. until the patient is afebrile, and then 0·75 g. b.d. for a further seven days.

In the present case it seems that the first course was inadequate, but, despite an intestinal hæmorrhage, the second course led to complete recovery.

Toxic Effects

Other workers report such complications as cerebral irritation, transitory erythemopapular rashes, nausea, anorexia, diarrhœa, and circulatory failure (Shah 1949, Vakil 1949). In the present case the first course was stopped because the patient's temperature fell to 95°F and he developed a coarse tremor; whether these were toxic effects it is difficult to ascertain. There is no doubt that the tremor disappeared twenty-four hours after cessation of the chloramphenicol, but it did not return with the second course.

SUMMARY

A case of typhoid fever treated with 16·5 g. of chloramphenicol in five days relapsed eight days after the end of the course, but a second course of 19·5 g. in six and a half days led to complete recovery. The patient developed a low temperature and a coarse tremor during the first course; these may have been toxic effects of the drug but they did not recur in the second course.

ABNORMALITY IN STEROID METABOLISM ASSOCIATED WITH RHEUMATOID ARTHRITIS

I. F. Sommerville
M.B., Ph.D. Edin.

G. F. Marrian
D.Sc. Lond., F.R.S.

J. J. R. Duthie

From the University Department of Biochemistry and the Rheumatic Unit, Northern General Hospital, Edinburgh

It has recently been shown by Hench et al. (1949) that rheumatoid arthritics respond dramatically to treatment with 11-dehydro-17-hydroxycorticosterone ('Cortisone') in the form of its acetate, at a dose-level of about 100 mg. per day. The high dosage required for the relief of the symptoms coupled with the fact that rheumatoid arthritics, as far as is known, do not exhibit any of the generally recognised symptoms of adrenal insufficiency, suggested to us that the condition might be associated with an abnormality in the metabolism of cortisone in the affected tissues, rather than with a deficient secretion of this hormone by the adrenal cortex.

Since the large quantities of cortisone necessary for a direct test of this hypothesis were unavailable to us, we considered that it might be profitable to study quantitatively in rheumatoid-arthritic subjects the metabolism of some more readily obtainable steroid closely related structurally to cortisone. We felt that although the discovery of an abnormality in the metabolism of such a steroid in rheumatoid arthritis would not prove the original working hypothesis, it would at least indicate the desirability of attempting a direct experimental investigation as soon as the supply of cortisone improves.

Progesterone was selected for this investigation in preference to the more closely related 11-deoxycorticosterone for two reasons: (1) at the high dosages which have to be employed in such steroid metabolism experiments the sodium-retaining action of the latter might have constituted a serious danger, whereas at these dosages progesterone produces no undesirable physiological or pharmacological effects apart from mild sedation in some instances; and (2) as a result of previous investigations by two of us (Sommerville and Marrian 1950) a considerable amount of information was already available concerning the conversion of administered progesterone into urinary pregnanediol in normal people.

EXPERIMENTAL PROCEDURE

Progesterone dissolved in arachis oil was administered to the subjects by intramuscular injection in two successive daily doses of 60 mg. Twenty-four-hour urine specimens (preserved with toluene) were collected from each subject during a preliminary control period of two ays, during the two days when the hormone was being dministered, and for the following four days. Each pecimen was made up to a volume of 2500 ml. with ater, and pregnanediol determinations in duplicate vere carried out on 500 ml. samples by the method of ommerville, Gough, and Marrian (1948). The total regnanediol excreted as a result of the administration of the progesterone was calculated after correction of the aily apparent pregnanediol excretion for the average control-period "blank."

Experiments were carried out on 9 postmenopausal women and 4 men suffering from rheumatoid arthritis, and on 6 normal postmenopausal women and 4 normal men.* Since some salicylates are known to be excreted in the urine in conjugation with glucuronic acid, the possibility had to be considered that these might in some way influence the excretion of pregnanediol by interfering with the formation of pregnanediol glucuronide. Accordingly salicylate therapy was withheld from all the arthritic subjects for from one to eight weeks before the experiments.

RESULTS

The results indicate quite clearly that rheumatoid arthritics of both sexes excrete in the urine as pregnanediol an abnormally high proportion of intramuscularly administered progesterone. The values given are calculated from the mean of the duplicate determinations. In every case satisfactory agreement between the duplicate determinations was obtained. The percentage of administered progesterone recovered as urinary pregnanediol was as follows :

	Normal	*Rheumatoid arthritic*
Men :	9·3	21·7
	10·0	23·8
	12·2	26·1
	14·7	27·4
Postmenopausal women :	12·1	19·0
	13·7	20·7
	15·2	22·0
	15·6	25·1
	15·6	25·7
	16·0	26·8
		31·0
		35·0
		36·4

Careful assessment of all clinical data revealed no clear-cut correlation between the severity of the disease and the percentage of administered progesterone excreted as urinary pregnanediol.

DISCUSSION

Until quantitative studies on the conversion of administered progesterone into urinary pregnanediol have been carried out in a wide variety of other clinical conditions, the importance of the present observations must remain in some doubt, since the abnormality in progesterone metabolism reported here may be more common than we now suppose. Furthermore, even though this abnormality should prove to be specific to rheumatoid arthritis and related conditions, it may be quite unrelated to the response of these conditions to cortisone therapy. Nevertheless, the discovery of an abnormality in the metabolism of progesterone in a clinical condition which yields to treatment with a closely related steroid hormone is not without interest ; and it now seems clear that our hypothesis that rheumatoid arthritis may be associated with an analogous abnormality in the metabolism of the adrenocortical steroid hormones deserves serious consideration and must be investigated experimentally as soon as circumstances permit.

Further speculations about the possible significance of the present results would be unwise at the moment since little is known about the metabolism of cortisone in the body, while the exact physiological significance of pregnanediol as a metabolite of progesterone is still very obscure.

Although there was no evidence of a correlation between the abnormality of progesterone metabolism and the activity of the disease process as assessed by the criteria available, further work may possibly reveal a relation between this metabolic abnormality and the fundamental pathogenesis of rheumatoid arthritis.

In the hope that others may wish to attempt the confirmation and further extension of our results, we wish to take this opportunity of pointing out that for quantitative studies of the urinary pregnanediol excretion following the administration of progesterone in doses of less than about 100 mg. per day, a method of pregnanediol determination at least as sensitive and accurate as that used in the present work must be employed. The difference in the pregnanediol excretions between normal and arthritic subjects reported here are quite definite, but it is doubtful whether they would have been observed if a less accurate and sensitive quantitative method had been used. In our opinion, older methods such as the original one of Venning (1937, 1938), or newer methods designed primarily for semi-quantitative routine diagnostic work, such as those of Guterman (1944, 1945) and of Sommerville, Marrian, and Kellar (1948), would be entirely unsuitable for quantitative studies on progesterone metabolism.

We wish to express our gratitude to the Medical Research Council for a personal grant to one of us (I. F. S.), and for a grant (to G. F. M.), from which the expenses of this work were largely defrayed. We owe much to the skilful technical assistance of Mr. D. W. Davidson.

* All but one of the figures for the excretion of pregnanediol by normal postmenopausal women and men following the intramuscular injection of progesterone are taken from a previous paper by two of us (Sommerville and Marrian 1950).

Preliminary Communication

ISOLATION OF A POLYPEPTIDE WITH HIGH ADRENOCORTICOTROPHIC ACTIVITY

We have previously reported[1] that, by ultrafiltration of pituitary-gland extracts under suitable conditions, it is possible to prepare a polypeptide mixture which has high adrenocorticotrophic activity, approximately 1·4 times as active as the homogeneous protein adrenocorticotrophic hormone of Sayers, White, and Long.[2] We have now separated from this mixture by fractional ultrafiltration and ionophoresis a peptide which appears to be homogeneous. Paper partition chromatography in phenol, lutidine, butanol-acetic acid, and propanol-acetic acid reveals only one peptide spot. Ionophoresis at pHs 2·3, 4·0, 6·0, and 8·0 indicates only one peptide component. More rigorous tests of homogeneity must await the isolation of larger amounts of the peptide. The adrenocorticotrophic activity of this material has been compared with that of the Armour standard adrenocorticotrophin preparation no. La-1-a by the adrenal ascorbic-acid depletion method of Sayers, Sayers, and Woodbury.[3] The results are :

Preparation	*Number of animals used*	*Dose (μg.)*	*Ascorbic acid depletion (μg. per 100 mg. adrenal tissue)*
La-1-a	3	0·3	29
	4	0·6	69
	4	1·2	134
Polypeptide	4	0·04	41
	4	0·08	97
	4	0·32	163

---

1. Crooke, A. C., Henly, A. A., Morris, C. J. O. R. *Int. physiol. Cong.* 1947 (Abstr.) 16, 139 ; Cortis Jones, B., Crooke, A. C., Henly, A. A., Morris, P., Morris, C. J. O. R. *Biochem. J.* (in the press).
2. Sayers, G., White, A., Long, C. N. H. *J. biol. Chem.* 1943, 149, 425.
3. Sayers, M., Sayers, G., Woodbury, L. A. *Endocrinology*, 1948, 42, 379.

Analysis of these data indicates that the polypeptide is 8·5 times as active as La-1-a, or approximately 10 times as active as the protein hormone of Sayers, White, and Long.

Until the constitution of the active material has been elucidated, we suggest that it be called "adrenocorticotrophic peptide" (A.C.T.P.).

Ultrafiltration at different pH values and paper chromatography of the various peptides isolated from the mixture, both singly and in artificial mixtures, indicate that, in the pH range near neutrality, the active peptide can associate with other components to form a larger molecule. This process appears to be reversible and suggests that A.C.T.P. exists as such in the protein hormone molecule.

Medical Societies

ROYAL SOCIETY OF MEDICINE AND SOCIETY FOR STUDY OF ADDICTION

Treatment of Alcoholism

ON Jan. 10 Dr. ERIK JACOBSEN (Copenhagen) read a paper on Biochemical Methods in the Treatment of Alcoholism, with special reference to 'Antabuse,' to a joint meeting of the Society for the Study of Addiction and the psychiatry section of the Royal Society of Medicine. Dr. W. J. T. KIMBER, president of the psychiatry section, was in the chair.

Dr. Jacobsen remarked that alcohol, like fire, was a good servant but a bad master. Why should it remain the servant for most yet become the master of a few? Some answered this question in terms of biochemistry, others in terms of psychology. Dr. Jacobsen warned against extreme views and emphasised that biochemical methods must be complementary to psychotherapy.

In the production of alcoholism there were external factors, such as bad social or family conditions and drinking habits. But there were also internal factors; and different workers attached importance to anxiety or Freudian complexes or psychopathic states. Some people could not help continuing to drink when they had taken a certain amount, which Dr. Jacobsen termed the "critical dose." In alcoholics this was small and therefore soon exceeded. Probably even in the individual alcoholic there was no single cause; but in some, external factors predominated, and in others the internal. Once developed, alcoholism was kept alive by a series of vicious circles—it led, for instance, to neuroses, which increased the internal psychological factors, and to a social decline which increased the external factors.

Many general practitioners—and even, Dr. Jacobsen admitted, some specialists—believed that it was sufficient to deprive the person of alcohol. Yet experience showed that this would produce only temporary abstinence; the importance of withholding alcohol should not be underestimated, but it was necessary to control all the factors.

This brought Dr. Jacobsen to the description of tetraethylthiuramdisulphide ('Antabuse').[1] If alcohol was taken after the administration of antabuse, the discomfort was usually so intense as to result in abstinence. In itself antabuse was quite innocuous; there were side-effects, but these disappeared as treatment continued and were not of practical importance. If, however, even small quantities of alcohol were taken, the person became red in the face after about 5–10 minutes and the vasodilatation might spread over the whole of the upper part of the body; the pulse-rate rose; and the patient had palpitations, a feeling of tightness about the neck, possibly nausea and vomiting, and a highly disagreeable feeling described by Dr. Jacobsen as like "a premature and very severe hangover." The effects included a sharp rise in the blood-acetaldehyde content which was responsible for all the effects.

Dr. Jacobsen described the results in 200 cases, mainly outpatients, observed by Dr. O. Martensen-Larsen.[2] The patient was first kept off all alcohol for a few days, so that none should be present in his system when antabuse was given. 0·5–1 g. antabuse was then given daily for 2–3 days, after which a small test dose of alcohol (equivalent to 1 oz. of whisky) was drunk in the presence of the doctor, to bring home to the patient the unpleasant effects. The dose of antabuse was adjusted in relation to the reaction and to the side-effects, and administration was continued for some months according to the needs of the patient. At the same time psychological and social treatment was given. The nature of the addiction was explained to the patient in terms of diabetes, and he was told that, just as diabetics had to avoid sugar, so he had to avoid alcohol; he was given every possible psychotherapeutic help. Group psychotherapy was found useful, and for after-treatment a group on the lines of Alcoholics Anonymous had been formed. Lastly a guardian (wife, friend, or employer) was appointed to watch over the patient and report if anything went wrong.

The 200 cases described by Dr. Jacobsen were unselected; 17 attended for so short a time that proper treatment was impossible, 16 had disappeared, and 3 had died. Of the remaining 164, 112 had been observed for twelve months and 42 for nine months. Of all the patients, 10% were women; and of the total, 90 had previously had some form of treatment. The results showed that 76% of patients under 35 and 44% over 51 were socially recovered. A wife could judge much better whether her husband had recovered than could a doctor who only saw him occasionally; and Dr. Jacobsen drew attention to the importance, for success, of the attitude of the patient and his relatives. The results indicated that the prognosis was best in young persons; and it became progressively less good with increasing age. This might be due partly to difficulty in getting older people to adjust their habits—it was, for instance, difficult to get a man who had spent all his life in public houses drinking with his friends to start collecting stamps.

In itself antabuse was no cure for alcoholism but an adjunct to other measures. In its administration the clandestine method, however attractive it might seem, was contra-indicated for three reasons: (1) the person might have a serious reaction through drinking alcohol when he did not realise that he had had the substance: (2) he would find out that he was being dosed (one man was now seeking a divorce on this ground); and (3) it should not be decided by a layman whether treatment for addiction was desirable. Antabuse should, therefore, only be used with the patient's full consent and coöperation.

Dr. Jacobsen described antabuse as producing "chemical confinement," whereas in the past the most effective way to prevent a man drinking was to lock him up. This "chemical wall" would not continue to stand of itself; and while it stood all other therapeutic steps should be taken.

One psychological result of alcoholism was fear of alcohol intake and its consequences. When a patient found that with antabuse he was unable to take alcohol he was greatly encouraged, but the physician must not be deceived by such early recovery. The patient might find that, although he had overcome the craving for alcohol, he met other difficulties; or he might, through over-confidence, stop treatment. For this reason there

---

1. See Hald, J., Jacobsen, E. *Lancet*, 1948, ii, 1001.

2. See Martensen-Larsen, O. *Ibid*, p. 1004.

was a critical period three or four months after treatment had started, and this was why there must be a guardian who could report such a development.

Antabuse could not be continued indefinitely; it was a matter of experience to judge how long it could be used. Therapy, Dr. Jacobsen concluded, must be individual.

Dr. H. J. **Pullar-Strecker**, hon. secretary of the Society for the Study of Addiction, said he was glad that the speaker had recommended simple common-sense psychotherapy which the patient could understand. Dr. Pullar-Strecker thought that for the patient who would do anything to throw off his handicap antabuse might be regarded, not as an adjunct, but as a therapy. Antabuse was a landmark in the treatment of alcoholism. In the same way that electroconvulsant therapy helped psychiatry in general, antabuse would help to dispel the notion that alcoholism was incurable.

Dr. M. A. **Partridge** said that little attention seemed to have been paid to the effect of antabuse on the blood-pressure.

Dr. A. E. A. **Carver** referred to the value of antabuse as an indication of whether a person under treatment had been taking drink surreptitiously.

Dr. R. **Orton** drew attention to toxic symptoms, consisting of diplopia and left facial palsy, and asked for an antidote to aldehyde poisoning. With the introduction of antabuse, patients could no longer pretend that they were trying to overcome their alcoholism when they were not.

Dr. J. A. **Hobson** compared apomorphine and antabuse. Antabuse made it impossible for the alcoholic to drink, because the effects of drinking were so unpleasant, but it did not affect his feeling of the need for alcohol. Apomorphine took away a craving for drink, yet left the person able to drink if he wanted to; and it was completely safe.

Dr. **Jacobsen** replied that in animals the toxicity of antabuse had proved very slight; no chronic ill effects had been observed, but some had been reported by other workers. Whilst acknowledging that there had been two or three deaths following administration of antabuse, Dr. Jacobsen pointed out that something like 20,000 people had been treated with it in Denmark, Sweden, and elsewhere. Several patients with angina pectoris had had antabuse and gone through the alcohol test without ill effect.

In acetaldehyde poisoning. use should be made of oxygen, or better still oxygen with 5% carbon dioxide. American workers had recommended ascorbic acid intravenously; saline might also be given, and hexobarbitone to make the patient sleep.

Reviews of Books

Diabetes and its Treatment

Joseph H. Barach, M.D., F.A.C.P., associate professor, University of Pittsburgh. London: Oxford University Press. 1949. Pp. 326. 50*s.*

Dr. Barach has written a big book, which "offers the general medical man a clinical approach" on diabetes and its treatment. This it certainly does, and very clearly; but one wonders what page the inexperienced practitioner should turn to in a hurry when faced with a new diabetic patient. Many useful diets are prescribed. in separate sections for men, women, and children, on a calorie-requirement basis, the highest for men being 30 cal. per kg. weight—on which, we should think, the Pittsburgh operative diabetic might fade out of working efficiency. Though the book will be of interest mainly to specialists, it is good and by an experienced clinician.

A striking difference is apparent between books on diabetes published in the United States and those published in this country. In the U.S.A. there are some four large works which, comprehensive though they are. give little help to the practitioner in setting about practical treatment, except perhaps by diet. In this country, on the other hand, we have many useful and simple books which cover this ground. In either country, when in doubt, the doctor should always be able to refer cases to a diabetic centre. At present these are hardly sufficiently widespread in the U.S.A., but the American Diabetic Association are keenly interested in the establishment of centres, and Dr. Barach is a leader in such activities. In Britain the new health service may provide the widespread centres necessary to make our 200,000 diabetics healthy working citizens.

Textbook of Histology

Jose F. Nonidez, D.SC., late professor of anatomy, Cornell University, and professor of microscopic anatomy. University of Georgia; William F. Windle, PH.D., SC.D., professor of anatomy, University of Pennsylvania. New York and London: McGraw-Hill. 1949. Pp. 446. 57*s.* 6*d.*

This is a good and indeed enjoyable book written by a man who knew just how he could help the student of histology. It is clear, concise, and up to date; the presentation is simple yet with an accentuation of important fundamentals, so that it will appeal not only to the young student but also to that perpetual student of histology the seasoned morbid anatomist, who can use it to refresh his memory. Dr. Nonidez had been working on this book for some time when, shortly after taking up his new appointment in Georgia. he died. Dr. Windle at once assumed responsibility for completing the project, and in the text which he has prepared he has kept faithfully to the original plan. The work is admirably illustrated with 209 drawings, many of them by Dr. Nonidez himself, and 193 photomicrographs, several of which are outstandingly good: they include up-to-date examples of phase-contrast microscopy as well as no fewer than fourteen from slides prepared by the late Prof. George A. Piersol over fifty years ago—a happy blend of the old and the new. Dr. Windle has produced a fitting memorial to his friend, for he has provided us with a simple textbook which will. as he intended, "elicit the abiding interest of the reader."

The Thyroid Hormones and their Action

G. Mansfeld, M.D., professor of physiology, University of Budapest. Translated by Erwin Pulay, M.D. London: Frederick Muller. 1949. Pp. 157. 24*s.*

For *the first time* a comprehensive account of Mansfeld's work on thyroid physiology is available to the English reader. This work, almost unknown over here, is based on numerous well-controlled experiments. extending over some thirty years. It has evolved on quite different lines from those followed by British and American workers on the thyroid, and the conclusions may seem surprising. Yet the strange views put forward in this book cannot be dismissed as mere speculation; on the contrary. each step in the argument is closely supported by experiments.

The title sufficiently indicates the wide divergences between Mansfeld's conception of thyroid function and that current in this country. To us, there is only one thyroid hormone: to Mansfeld, there are several. There is the hypothetical hormone which he thinks is concerned with the maturation of red cells. Then there are the "thermothyrins" A and B, which antagonise the metabolic effects of thyroxine and are, according to Mansfeld, of prime importance in the normal control of heat regulation. These last two hormones have been isolated and their empirical formula determined. Mansfeld also holds that the colloid has a physiological function quite apart from its thyroxine content. The study of thyroxine itself has by no means been neglected: Mansfeld has investigated its mode of action on cells and the pathways by which it reaches them. Here again his views are heterodox, for he has found evidence which suggests that thyroxine passes from the blood to the central nervous system, whence it reaches the tissues by way of the peripheral nerves.

The greater part of the book describes physiological experiments and the deductions to be drawn from them. The final chapter is on Graves's disease; here the argument keeps less strictly to verifiable facts and will not carry much conviction in this country. The translator's prose has a strong resemblance to English and is usually comprehensible.

Tuberculosis Nursing

JESSIE G. EYRE, senior sister tutor, St. Helier Hospital, Carshalton, Surrey; formerly sister tutor to Chity Sanatorium, Birmingham. London: H. K. Lewis & Co. 1949. Pp. 292. 21*s*.

THIS book will prove valuable to nurses who are caring for cases of pulmonary tuberculosis, especially those in institutions where surgical treatment is done on a large scale. The general set-up is good, and the instructions given are clear and thorough. In writing a book of this kind, the author is at once faced with the problem of how much to leave out and how much to put in. On the whole, a happy compromise seems to have been achieved, the emphasis being laid on hospital nursing. A little more detail on the psychological side of nursing in sanatoria would be helpful. It is perhaps unfortunate that the patch test should be advocated, since most workers have now decided that this is unreliable and have discarded it in favour of the tuberculin-jelly test. The method suggested for the use of B.C.G. is not that recommended by the Ministry of Health for routine use in England. No special instruction is given in the care of a nurse's own health, and disinfection is treated in three different places. A number of nursing procedures common to all nursing could be spared to make room for fuller sections on such important topics. But such omissions will doubtless be remedied in future editions; meanwhile the book can be recommended with confidence to all nurses dealing with tuberculous patients, though the publishers would have been wise to sacrifice some of the volume's sleekness in consideration for the average nurse's pocket.

Studies in Preventive Medicine

HAVEN EMERSON, A.M., M.D., D.S.M., professor emeritus of public-health administration, Columbia University, New York. Battle Creek: W. K. Kellogg Foundation. 1949. Pp. 507. $3.

Dr. Haven Emerson is well known to workers in preventive medicine in this country. In the second decade of the present century he was health commissioner of New York City, and later he was for many years professor of public-health administration in the Columbia University. His seventy-fifth birthday was on Oct. 19, 1949; and the W. K. Kellogg Foundation, of which he has been a trustee for 14 years, celebrated this by publishing 35 papers selected from his writings during his long, strenuous, and varied career. The papers range over a wide field of professional activity, including laboratory studies and contributions to clinical medicine, epidemiology, vital statistics, social medicine, and public-health administration. On all these subjects Dr. Emerson has much to say that is well worth hearing and ruminating on. He shows that though, since the beginning of the century, great advances have been made in our knowledge of diseases, there has been a considerable lag in applying new knowledge to their control. For him, two of the most powerful enemies of the public health, against which Western civilisation has hitherto not launched a really effective attack, are alcohol and venereal diseases. A most interesting paper describes the incidence of tuberculosis in the Emerson family during their 311 years of continuous residence in America, and covers eleven generations in the direct male line. In the first five generations (1638–1776) there was no evidence of tuberculosis; in the next five (1811–1938) there were 5 fatal and 9 non-fatal cases; but no case has yet appeared in the eleventh generation (1933+). Dr. Haven Emerson himself developed pulmonary tuberculosis when he was 36, but recovered under the care of Dr. Trudeau. His illustrious forbear, Ralph Waldo Emerson, contracted tuberculosis while a student at Harvard, but recovered and died at the age of 79 of circulatory disease. The book is interesting from beginning to end. It reveals a wise, strong, and dynamic personality, and is written with a literary charm that was to be expected from a member of a family so distinguished in the world of letters.

Clinical Electroencephalography

ROBERT COHN, M.D., *electroencephalographer and director* of neurological research, U.S. Naval Hospital, Bethesda, Maryland. New York and London: McGraw-Hill. 1949. Pp. 639. 119*s*.

THIS expensive and bulky atlas contains samples of E.E.G. records from nearly 300 patients. The text is limited to two dozen pages of introduction to the clinical interpretation of the E.E.G., and to case-summaries which face the records—a massive accumulation of undigested material. A few of these cases, with some reference to the valuable work done in this subject in the past 15 years, would have attracted and stimulated the intending worker. These hundreds of pages of records cannot be a substitute for personal experience, and will deter any but the most stolid. What is needed today is a textbook covering the physics, physiology, and clinical aspects of electro encephalography, as well as some guiding principles, based on fundamentals, and presented with illustrative examples. These would help in the training of a clinical electro-encephalographer. The subject is already overloaded with uncritical description such as this.

Ictericias y Laboratorio

HECTOR DUCCI CLARO, auxiliary professor of medicine University of Chile, Santiago. Santiago: University o Chile Press. 1949. Pp. 196.

THIS short monograph in Spanish is concerned wit the biochemical investigation of jaundice. After concis accounts of the causes and salient features of the variou types of icterus, the author describes the individua diagnostic tests. All the current flocculation tests ar critically considered and the growing work on the subjec carefully annotated. The tables on pp. 55 and 96 ar particularly valuable and give a good summary of th present position. Dr. Ducci's own contribution consists i the findings of the flocculation tests, for serum citri acid and for serum alkaline phosphatase, in a very larg series of jaundiced patients. His results agree with thos previously published. The bibliography is comprehensive and the book well produced; it will be of little interes to the general reader, but can be recommended for the specialist interested in liver disease and in particular for those working on flocculation tests.

Schildrüse und Basedow

Prof. Dr. Med. WILHELM EICKOFF, M.D., of Rheine, Westphalia. Stuttgart: Thieme. 1949. Pp. 125. D.M. 10·80.

WILD rabbits, when taken captive, pine away and die. Eickoff's clinical and pathological studies of this interesting phenomenon have convinced him that the process is the same as human thyrotoxicosis. If the rabbits are treated with methyl thiouracil from the time of capture, they survive and gain weight. Various ingenious observations on this and other species of wild animal lead to a discussion of the factors governing thyroid function in the natural state. The approach is decidedly original and not unpromising, but the rather scanty facts so far discovered are overburdened with hypothesis.

Handbook of Bacteriology (6th ed. London: Baillière, Tindall, and Cox. 1949. Pp. 547. 20*s*.).—"The most unwilling student," Prof. Joseph W. Bigger writes in the preface to the new edition of his well-known book, "could not regret more than I the increase in the text from 455 to 535 pages." He has worked hard at pruning, compressing, and revising, but new discoveries will keep breaking in. Penicillin and the sulphonamides, mere infants when the last edition appeared in 1939, have sprung up, and are now among the giants of bacteriology, occupying two full chapters. The viruses and rickettsiæ are of course multiplying rapidly. Five chapters on immunity, three on intestinal bacteria, and one on undulant fever have been rewritten; and the revision of the whole book is described as the most thorough in its history. It has always been a favourite, and continues to deserve its honours.

THE LANCET

LONDON: SATURDAY, JAN. 21, 1950

The Brachial Palsy Hazard

DESPITE the old saying that a change is as good as a rest, few patients really relish exchanging one disorder for another. To go into the theatre with uterine fibroids and come out with brachial palsy has lately become quite a common accident. Indeed, one patient in a gynæcological ward who complained of moderate weakness of her right arm was admonished: "You're lucky: look at Mrs. So-and-so—she has to take hold of hers with her left hand before she can move it at all." Though it is easy enough to say that most of these palsies clear up in six months or so, the patient may suffer considerable hardship during that time. Most of the cases reported have been in the right arm, presumably because, from the surgeon's point of view, this is the more convenient arm for the anæsthetist to use for intravenous medication. But a labourer whose right arm is weakened even temporarily may find it difficult to get work. Fine finger movements may take even longer to return than power in the larger muscles. We have heard of one commercial artist whose former firm line is now tremulous, though more than a year has passed since the operation. A teacher of sewing had a comparable experience; and it is easy to see how such a disability could hinder the livelihood of many others—pianists, instrument-makers, joiners, typists, embroiderers, and watchmakers, to name a few. In none of the cases of which we have heard was the patient asked before operation whether he was right-handed or left-handed; yet this simple precaution alone should have made it possible to spare the earning hand. The lesion is not merely troublesome: it is uncomfortable too. In his article on another page Dr. KILOH mentions aching pain in root distribution and tenderness of muscles. This aching, patients report, is brought on by using the arm, and by weather changes. They find they have to favour the bad arm, carrying parcels in the other hand and protecting it from extremes of heat and cold—a constant tiresome reminder of someone else's carelessness.

The cases reported this week by Mr. EWING and by Dr. KILOH show that gynæcological operations are not alone to blame; brachial palsy can follow any operation provided a small group of factors are present. The patient has always, or nearly always, been given a curariform drug, he has often been placed in the Trendelenburg position, and his arms have generally been abducted, extended, and externally rotated. This combination of events, it seems, could hardly have been better designed for putting the brachial plexus on the stretch, and perhaps for compressing it as well between the first rib and the clavicle. In the Trendelenburg position the shoulders are supported by rests, and the weight of the body, thrusting down from above, forcibly depresses the shoulder-girdle against the action of the structures which sling it from the trunk—the brachial plexus among them. In a conscious person, as Mr. EWING shows, the tonic contraction of the trapezius and the rhomboids will protect the nerve-trunks from strain, temporarily at any rate; but in an anæsthetised and curarised patient things are very different. The muscles, agreeably toneless for the surgeon, are lost allies for the patient; they take no strain at all. Nor is the surgeon the only one whose convenience must be studied; since intravenous medication or transfusion may be necessary, the anæsthetist naturally likes to have the patient's veins convenient to his hand. The flaccid arms are therefore usually supported on a board pushed under the rubber mattress on the operating-table; which means they are not only abducted to a right-angle, extended, and externally rotated, but are usually sloping from the shoulders to a horizontal level slightly below that of the rest of the body. In this position of the limb, the head of the humerus is thrown into prominence, and tightens the stretched plexus as a bridge tightens fiddle-strings. In a gall-bladder operation the tension may be increased still further by extending the patient's back over a double wedge. And finally some additional tension may be secured—though the evidence is not conclusive—if the anæsthetist for some good anæsthetic reason turns the patient's head to the opposite side. The lookers-on must also be catered for: they press in between the arm and the body, pushing the supporting board askew, until the right-angle becomes obtuse.

The case for compression is not so clear, but Dr. KILOH thinks there has been at least one unquestionable example where a brachial-plexus lesion after the use of the Trendelenburg position was due to direct pressure from an inadequately padded shoulder-rest. DENNY-BROWN and BRENNER, however, as Mr. EWING notes, have shown the primary cause of damage to a nerve by pressure to be the result of ischæmia due to obliteration of its vessels; and they found it very hard to cause such a disturbance in large nerve-trunks. This may be easier to do, however, in a nerve which is already stretched; and as Dr. KILOH says, idiosyncrasy may come in: "the slope of the shoulders, the size of the first rib, and other individual anatomical peculiarities, all within the limits of normality, may in combination render the brachial plexus vulnerable to pressure or traction."

But the causes of this condition, fascinating as they are, surely deserve less serious attention than the fact that it can be avoided. The extreme Trendelenburg position and complete muscular relaxation certainly make gynæcological surgery easier; they are much favoured in America where brachial-plexus lesions after their use have been described for a long time past. The fact remains that, if the slope is steep, it is difficult to find a harmless way of anchoring the patient. If he is suspended from the knees he is liable to develop thrombosis in the leg vessels, and at least one amputation for gangrene has been necessary. Shoulder-rests carry the risks we have been discussing, and a suggestion that the patient should be suspended from the iliac crest by special holders seems to have appealed as little to surgeons as it probably would to patients if they were asked. In any case few conscious people over the age of 40 care for standing on their heads for even a moment. To hang upside down for an hour or more would doubtless make them feel exceedingly ill, and there is no reason to suppose that because consciousness is absent the body finds the experience more acceptable. Thanks to curariform drugs, the extreme Trendelenburg position is now rarely—possibly never—needed; and even a mild degree of tilting should be maintained for as short a time as possible. Some surgeons take the precaution of waiting till they have opened the peritoneum before allowing the patient to be tilted at all.

"In no circumstances," Mr. EWING says, "must the arm be abducted with the patient in this position." This maxim should be strictly followed. He shows that the claims of the anæsthetist can, with a little ingenuity, be met when the arms are at the sides. Mr. BRYAN WILLIAMS tells us that in his clinic they have had no cases of brachial palsy associated with the Trendelenburg position since they gave up abducting the arm. Now that the causes and methods of prevention are clearly before us, every surgeon should feel his credit engaged to ensure that no further cases develop among his patients. He would himself think the cost of recovery after an operation very high if he paid for it with his dexterity.

The Malignancy of Nodular Goitres

NODULAR goitres are common, even outside the classical endemic areas, and a proportion of them become malignant. How often this change occurs, and the measures to be taken to deal with or forestall it, have been the subject of much debate. The surgical opinion in the United States [1] is that nodular goitres are more frequently malignant than has generally been supposed and consequently should be more freely operated on. The article by BRANSON and HOUSTON,[2] in our columns a few weeks ago, shows that the same view is now held by some British surgeons; indeed, the writers go so far as to recommend the removal of all nodular goitres, irrespective of symptoms or size. The evidence on which this opinion is based deserves careful examination. BRANSON and HOUSTON reviewed 530 cases of nodular goitre which had been under the care of the late Mr. CECIL JOLL in 1931–44. Among these cases there were 33 malignant adenomas and 32 thyroid cancers of other types. Assuming that all the malignant adenomas, and some of the other cancers, arose in a pre-existing goitre, it appears that 6–12% of all their nodular goitres were malignant. In many of these malignancy was not suspected before operation. The nodular goitres were treated by partial thyroidectomy, followed by irradiation, with excellent results. Since the operative mortality was low, BRANSON and HOUSTON conclude that all non-toxic nodular goitres should be surgically removed.

Many surgeons will undoubtedly agree with this argument, but some surgeons and pathologists hold a contrary view. Broadly speaking the critics would raise two objections—they would have doubts about the histological diagnosis of malignancy, and they would contend that the cases were not truly representative of the general run of nodular goitres. On the question of diagnosis, GRAHAM and VAUX might be quoted, since BRANSON and HOUSTON adopted their criteria in arriving at a histological diagnosis. The greatest difficulty lies in distinguishing benign from malignant adenomas. Here BRANSON and HOUSTON relied on GRAHAM'S [3] paper of 1925. In 40% of the cases classed as malignant adenomas the diagnosis was made highly probable by the close relation of the neoplastic cells to vascular endothelium, often with actual invasion of the lumen. In the remaining 60% the diagnosis was based on morphology—that is, on the character and arrangement of the thyroid epithelium—and here the distinction between benign and malignant adenomas is less obvious; indeed, some authorities [4] [5] say that no hard-and-fast line can be drawn. It is noteworthy that VAUX,[5] in reporting on 13 malignant adenomas from the same series as BRANSON and HOUSTON, looked on close apposition of neoplastic cells to the vascular endothelium as the most reliable indication of malignancy; this was present in all her cases. Moreover GRAHAM [6] writing in 1933 about 186 cases previously diagnosed as malignant adenomas, felt compelled to reclassify 108 cases as benign, because they had survived for six or more years without recurrence. All the cases which he reclassified had been diagnosed on morphological grounds alone. It is likely that GRAHAM would regard the fact that all 50 of BRANSON and HOUSTON'S "malignant adenomas" survived for five years or more (after only a partial operation) as evidence that some were wrongly diagnosed in the first instance.

The other objection might come from CRILE.[7] He also has found a high incidence of malignancy among the nodular-goitre patients who have had a thyroidectomy; but he maintains that such figures cannot be applied to nodular goitres as a whole. The nodular goitre which comes to operation has been carefully screened: first by the patient (who seldom seeks advice for a small and static lump), then by the general practitioner, and then by the surgeon. CRILE is impressed by the fact that 4% of the patients admitted to the Cleveland Clinic for non-thyroid disease were found to have nodular goitres; no treatment was advised for these goitres. By an ingenious (though not necessarily reliable) calculation he surmises that operating on everyone who has a nodule in the thyroid would mean doing 6675 thyroidectomies to prevent 1 death from thyroid cancer. Accepting BRANSON and HOUSTON'S figures for operative mortality this policy would involve about 40 operative deaths for every patient saved from cancer. Speculative calculations of this kind should not be taken too literally; but this one shows that the critics of the policy have reasons for their opposition. Before all nodular goitres could be removed there would have to be a mass survey to bring to light all the

eople with such goitres who never seek medical dvice. If Branson and Houston really advocate uch drastic measures they must make out an unassailble case; and they must show that their proposed emedy is less lethal than thyroid cancer itself, which ills about 300 people a year in this country. Until hey have brought forward stronger evidence it might be better to adopt Crile's [7] policy. He holds that the linician should learn to be suspicious of the particular ype of goitre which is most often malignant and oncentrate his efforts on seeing that such cases are ffectively treated.

Polio's Cousins from Coxsackie

It is well recognised in North America that several viruses can produce clinical manifestations like those of poliomyelitis, and that in research work somewhat elaborate laboratory investigations are therefore necessary to verify a clinical diagnosis of poliomyelitis. Now Dr. Gilbert Dalldorf, director of the New York State Laboratories, Albany, and his associates [1] have separated off yet another virus infection which must be considered in the differential diagnosis. This virus was first isolated from patients in the village of Coxsackie in New York State in 1947. In that year workers in various parts of North America reported that mild attacks of what was accepted at the time as non-paralytic poliomyelitis were unduly prevalent in relation to the number of frankly paralysed cases. Sabin [2] in Cincinnati and Rhodes [3] in Toronto were able to recover only comparatively few strains of poliomyelitis virus from these mild illnesses, and in retrospect it seems possible that some of the suspected poliomyelitis cases were in fact infected with the Coxsackie virus. Melnick and his co-workers [4] in Dr. John Paul's department at Yale University, who have played a notable part in the investigation of this new disease, have isolated the virus from cases in Ohio, North Carolina, Texas, Rhode Island, and Connecticut; and Jaworski and West [5] have described the clinical features of some of the cases.

It appears that there are several antigenic types of the Coxsackie virus; so it is more accurately described as the "Coxsackie group of viruses." The main biological character of these viruses is pathogenicity for suckling mice and hamsters, older animals of these species, as well as monkeys and other animals, being insusceptible. These properties are in sharp contrast to those of human poliomyelitis virus of the rodent (Lansing) or monkey pathogenic types. The apparent primary lesion in suckling mice is in the skeletal muscles, where there is extensive involvement of striated fibres, with swelling, hyaline or waxy change, and loss of transverse striation. In some areas the fibres disappear completely. There is a well-marked proliferation of the cells of the sarcolemmal sheath, but no frank inflammatory exudate. Coxsackie viruses have been isolated from the stools and nasopharyngeal secretions of patients with illnesses characterised by "meningeal" irritation and diagnosed as non-paralytic poliomyelitis or aseptic meningitis. They have also been recovered from patients with brief febrile illnesses and can evidently cause a muscular weakness. Laboratory infections have occurred.[4, 6] Antibody develops in convalescence, but titration of antibody level presents technical difficulties. With regard to the association of this new virus with that of poliomyelitis, Melnick [4] mentions the recovery of both agents from pooled fæcal specimens and flies. Very recently, Nelles Silverthorne, A. J. Rhodes, and their associates [7] at the Hospital for Sick Children and the Connaught Medical Research Laboratories in Toronto have isolated both Coxsackie and human poliomyelitis viruses from the separately collected stools of three children, contacts one of another. They also refer to the isolation of Coxsackie viruses from three adults who had been in contact with these children, and from another child in whom the clinical diagnosis was Guillain-Barré-Landry ascending paralysis.

It is evident therefore that infections with the Coxsackie group of viruses are widespread in North America. It remains to be seen whether the reported association of human poliomyelitis virus and Coxsackie virus in individual patients is commonly observed; it is certainly far from universal. The association raises some interesting questions. For example, is it possible that one infection immunises against the other, or that one virus exerts an interfering or blocking effect on the other? The answers may solve several outstanding puzzles in the ætiology, pathogenesis, and epidemiology of "poliomyelitis." Meanwhile there is more justification than ever for insisting that a diagnosis of poliomyelitis, especially the minor (abortive) or non-paralytic (meningeal) varieties, can only be tentative until confirmed by laboratory tests.

How Do Drugs Act?

Chemotherapeutic drugs are valuable because they are more toxic to parasites or pathogenic bacteria than to the tissues of the host: they poison the disease and the patient recovers. Many other substances are relatively harmless to man but poisonous to certain undesired beings such as insects, rats, or weeds; and some time ago the Society for Experimental Biology held a symposium on this large subject of selective toxicity. The proceedings have now been published.[8]

Drugs, it is now realised, act by a very complex process involving a number of stages, the events at each stage depending on those in the previous one. Of the many stages, two in particular have lately been studied. One of these is the action of drugs at the surface of the cell, to which attention was first drawn in the Overton-Meyer theory of narcotic action. With the modern conception of surface membranes composed of elongated molecules orientated in a particular direction, this theory has been elaborated; and it is now widely recognised that one way in which a small amount of a chemical substance can prove toxic is by interfering with the surface structure of the cell. The other process singled out for study is the action of drugs as selective poisons to enzymes. Well-known examples of these are fluoride and cyanide (the latter inactivates cytochrome oxidase); but heavy metals such as mercuric salts and arsenicals act in the same way, combining with essential —SH groups in the tissues. The work of Prof. R. A. PETERS, F.R.S., and his associates has elucidated some of the mechanisms accounting for the extreme toxicity of lewisite and other arsenical poison gases and lacrimators; it has also provided the antidote, dimercaprol (BAL), which forms a stable compound with these poisons and so diverts them from the tissues.

[8] Symposia of the Society for Experimental Biology. No. 3: Selective Toxicity and Antibiotics. London: Cambridge University Press. 1949. Pp. 372. 35s.

The symposium showed that much has been done to elucidate the mode of action of the two great modern remedies—the sulphonamides and penicillin. In 1940 D. D. WOODS found that sulphanilamide interferes somehow with the utilisation of *p*-aminobenzoic acid. It is now known that an important part in cell metabolism is played by folic acid, which is a complex of glutamic acid, *p*-aminobenzoic acid, and pteridine nuclei; and sulphonamides act against certain bacteria by preventing the synthesis of folic acid from *p*-aminobenzoic acid. Yet these certain bacteria do not include the common sulphonamide-sensitive pathogens; and WOODS is forced to conclude tha inhibition of bacterial growth by sulphonamide cannot be satisfactorily explained solely by thei effect on the synthesis of folic acid. Th problem of how penicillin acts, and why it acts o gram-positive bacteria more than on gram-negativ organisms, is still largely unsolved; but a valuabl contribution is made by E. F. GALE. According t him, gram-positive bacteria are peculiar in being abl to concentrate amino-acids from their environment and this assimilation is bound up with a ribonucleotide complex, which is responsible for the positive gram reaction. He suggests that penicillin exerts a direct effect upon nucleic-acid metabolism within the growing cell, and possibly this impairs the power to assimilate amino-acids.

Annotations

A.C.T.P.

THE field of research opened up by Hench and his colleagues at the Mayo Clinic is being marked out almost day by day. In this issue Dr. and Mrs. Morris report from the London Hospital the isolation from pituitary-gland extracts of a peptide, named by them A.C.T.P., which appears to be homogeneous and has 8·5 times the activity of a standard American preparation of adrenocorticotropic hormone (A.C.T.H.). Whether this finding materially brightens the prospects of synthesising an active agent will depend on the nature of the peptide and the number of amino-acid residues; but the discovery should certainly bring nearer the production of A.C.T.H. of standard potency. As we mentioned on Jan. 7, one or more peptides with A.C.T.H. action have lately been isolated in California by C. H. Li.

On other pages Professor Marrian and his colleagues in Edinburgh report that in rheumatoid arthritics an abnormally high proportion of intramuscularly injected progesterone is excreted in the form of pregnanediol; and a Polish worker, Dr. Landsberg, describes a development in the technique described by Lewin and Wassén,[1] who relieved the manifestations of rheumatoid arthritis by injection of ascorbic acid and deoxycortone acetate. Dr. Landsberg has achieved similar results using other sterones (progesterone and testosterone) in place of deoxycortone.

OUTWORK

'UNWOMANLY' rags have gone out in Great Britain, along with much poverty, most hunger, and a certain amount of dirt. But piece-work—or outwork—goes on, though not on the wretched terms so rightly denounced by Tom Hood. Its effect on the sociological conditions of the workers, especially those who do it in their homes, has lately been studied in St. Pancras by the members of a seminar of the London School of Hygiene and Tropical Medicine. Their report ("Outwork"), which has not been published, is based on work done between January and March, 1949. Registered outworkers in the borough numbered 328 at that time: 185 of them were interviewed by members of the seminar and 124 by members of the staff of the St. Pancras public-health department, while 19 proved to have given up outwork. The department had been troubled over a possible rise in the number of outworkers, the names on the register having increased from 200 in 1945 to 577 in 1947. The findings of the seminar suggest that this was a temporary peak and that the rebuilding of factories after the wa and the improved supply of whole-time workers ha already reduced the amount of work put out.

The ordinary outworker gets on fairly well—or cause little trouble, as the St. Pancras council put it. Bu there are some outworkers who take in work not onl for themselves but for their whole family, and sometime other people. The contracting outworker then become in effect a factory owner, and even—if the industry lend such things as electric sewing machines—a power factor owner. A power factory in an overcrowded, under ventilated, poorly lighted St. Pancras basement, with inadequate sanitation, can cause a good deal of trouble

The seminar suggest that the term outwork should be used generally to cover all forms of work put out by a factory or shop; and that "homework" should be the term applied to work done by people in their own homes They have little but good to say of homework; for, though it is rewarded by relatively low hourly rates of pay, it offers some people—especially the housewife with one small child, the disabled worker, and the elderly—the chance to add to the family income and increase domestic comfort. It can be done at times convenient to the worker; and if it is work requiring special skill, such as embroidery or the handmaking of shoes, it is unsuitable for the mass-production methods of factories. Wearing apparel, including boots and shoes, gave occupation to no less than 208 people on the register; others made boxes, paper bags, handbags, brushes, artificial flowers, Christmas novelties, coat-hangers, electrical fittings, wigs, or umbrellas, or were concerned with soft furnishings, household linen, embroidery, furs, plastics, or buttons. There was no evidence of overcrowding among true homeworkers, and the condition of their homes depended not on whether they did homework but on whether they were any good as housewives. Weekly earnings ranged from 10*s*. to £3 a week, according to the ability of the worker and the time that could be spared for the work. The money was often spent on such amenities as cigarettes, extra clothes, table delicacies, or entertainments. A few people depended entirely on homework for their income, and a larger group would have been badly off without it. Only a few cases of sweated labour were seen. Children took no part in homework in any of the cases visited; and there was no evidence that the health of homeworkers was adversely affected. The seminar conclude that homework fulfils a useful function, both for the employer and the worker. They wisely insist, however, that outwork done in a workshop should be supervised under the Factories ct, 1937, as work done in a factory, and that the osition of the contractor who hands outwork to others equires further scrutiny.

TASTE SENSITIVITY TO PHENYL THIOUREA

THE observation that phenyl thiourea tastes bitter o some people but is tasteless to others was first made y Fox[1] in 1932. This odd finding was taken up by eneticists and it soon became apparent that the ability o taste phenyl thiourea is inherited in a simple way; whether a person is a "taster" or "non-taster" depends olely on the constitution of a single gene pair. "Tasters" are homozygous or heterozygous for the dominant allele.

According to numerous independent observers about 25–35% of people of European stock are "non-tasters." This proportion is surprisingly constant, which suggests that there is no particular biological advantage in being either a "taster" or a "non-taster"; and in that case the differential taste-response must be regarded as a biological curiosity of no practical importance. But recent work shows that the phenomenon cannot yet be summarily dismissed as having no significance for medicine. Harris and Kalmus[2] have assembled the known facts about the chemical grouping necessary for the differential taste response and have added much new information of their own. They make the generalisation that all the substances which give the phenyl thiourea type of response contain the same $=N-\underset{|}{C}=S$ group as the goitrogenic (antithyroid) substances. If a person is a taster for phenyl thiourea he is also a taster for thiourea, thiouracil, and a whole range of similar goitrogens. This generalisation might be of purely academic interest were it not for the fact that many of these goitrogenic substances are found in plants, some of which form part of our normal diet. Indeed Astwood[3] has made out a strong case for supposing that the ingestion of this type of substance is of considerable importance in the causation of goitre. If we accept his view, it would be reasonable to expect tasters and non-tasters to react differently to the presence of goitrogenic substances in their diet. Ability or inability to taste these substances might conceivably affect the amount of goitrogenic vegetables consumed; or, more probably, it might be an indication of the way in which these substances are metabolised. If the specialised taste-buds react in two different ways, then other tissues might do so also.

Harris, Kalmus, and Trotter have investigated the taste-reactions of a series of cases of goitre and they lately reported their results in a preliminary communication.[4] They found a normal proportion of non-tasters among cases of toxic diffuse goitre; but among cases of nodular goitre—whether toxic or not—there seemed to be an excess of non-tasters. Unfortunately the level of statistical significance attained was not decisive, so it would be premature to draw conclusions from their work until they have extended it or it has been repeated elsewhere. All that can be said is that the differential taste response may yet turn out to be of medical interest.

Meanwhile, some American work, on different lines, suggests that the physiological mechanism of taste may be more complex than had been supposed. Cohen and Ogdon[5] claim that even "tasters" cannot taste phenyl thiourea when a saturated solution is placed on a previously dried tongue; nor can they taste it when it is dissolved in another person's saliva, whether that person is a "taster" or not. Only when the phenyl thiourea is dissolved in the "taster's" own saliva does the bitter taste become apparent. Cohen and Ogdon conclude that "salivas are probably as different as fingerprints," but the evidence they present scarcely justifies such a sweeping conclusion, for no saliva from any person was used for more than one test on more than one subject. The technique too is open to criticism in that the subjects' tongues were dried by blowing air over them; this would evaporate the water but leave behind the solid constituents of the saliva which would probably redissolve when the phenyl thiourea solution was placed on the tongue. In any case, placing solutions on the tongue is a precarious method of taste-testing, for the results depend entirely on whether the solution reaches the taste-buds on the back of the tongue. In short, these experiments will have to be repeated with a more satisfactory technique before any firm conclusions can be drawn from them.

OLD PEOPLE AT SALFORD

SYMPATHY for old people is nowadays expressed less in elegant sentiments than in good hard work. Salford has done much already for the welfare of its older residents, and plans to do more. At an informal conference,[1] arranged last November by the mayor (Councillor C. R. V. Haynes, J.P.), Sir William Douglas recalled that between 1931 and 1947 those over the age of sixty-five rose from 7·4 to 10·9% of the population of this country; and in the latter year, some 13·7% of the population were of pensionable age. By no means all of these elders depend on public care for their comfort: only about 5% are in hospitals or institutions, and many of the remainder live with their families. But there are many, too, who live alone and need help of various kinds.

Meals-on-wheels are among the best services which these lonely old people can be offered. Miss S. Doherty, domestic help organiser, described the scheme running in Preston. She spoke of a heated metal cupboard in the transport van, of warmed containers to receive the food prepared at the civic restaurant, of the sparkling cleanness of the equipment, the server's fresh white overall, and the white towel in which she carries the hot container to the door; but more important to the old person than the meal (though that is interesting enough) is the chance to talk to someone friendly—a break in the day's monotony, something to look forward to. The home help and the home visitor bring the same kind of pleasure. Miss Bessie Chadwick told of the work done by the 62 home helps employed by the Salford corporation, not all of it paid work. The home helps become attached to the old people they look after. One goes nearly a mile nightly to tuck up her old lady for the night, another sends her child in to run messages on the days she does not go herself, a third left a dance during a storm to sit with her old lady, who was afraid of thunder. The Salford Good Neighbours Association has 29 volunteers, some of them men, who visit old people for a chat, and help them with small jobs. A retired naval man scrubs, sews, darns, and washes; a hairdresser gives a free haircut in the course of an hour's gossip. Miss C. E. Smith, a health visitor, mentioned the need for laundry services for old people; and suggested, too, that public-bath attendants might visit the homes to bathe old people; or perhaps transport might be arranged to take them to the public baths where the attendants could help them to bath themselves. She also mentioned the care of their feet: much of the difficulty which old people experience in getting about comes from foot troubles, and they need regular visits from a chiropodist.

Old people's clubs have proved their worth for many lonely old people. In Salford there are some 3500 old people living alone, and many of them already belong to clubs. The first of these was opened about two years

ago; but at the time of the conference there were already 20 in action. At one club with a membership of about 80, the average attendance, on the weekly club night is 60–65. The entertainment is simple but evidently satisfying—" the men play cards and dominoes and the ladies sing and dance," as one speaker put it; and there are concerts, outings, and entertainments, and social afternoons.

For those who are no longer fit to live entirely alone, Salford, like other places, is beginning to open residential homes, taking over big old houses for the purpose. There are now 11 houses open for women, with 78 residents; and similar homes are needed for men. The mixed homes which have proved such a success in many places were not mentioned as a possibility.

The Manchester and Salford Family Service Unit contribute to the symposium a telling little note on the care of the " problem aged." The unit undertakes to pay regular visits and give practical help to such people, many of whom through apathy and despair are " ending their days in loneliness and squalor." The unit workers clean and decorate, repair furniture, disinfect, shop, cook, arrange for washing to be done, find new clothing and bedding, and help with a move to better quarters when this is possible. They promise a complete account of their experience, which will surely be widely read.

PROFESSOR RYLE'S RETIREMENT

Prof. John Ryle's career reflects the changes which medicine as a whole has undergone during the present century. He comes of a family which has achieved distinction in religion and philosophy, and he has consistently deprecated the narrow technical approach to medical problems. The first phase was the normal development of a consulting physician, beginning with the physiological studies on gastric secretion, which have made the name of Ryle familiar to every medical student, and culminating in the lectures on clinical phenomena which were finally published as the *Natural History of Disease.* His contributions to knowledge of the visceral neuroses were especially noteworthy.

His abilities as a clinical research-worker and writer, and his success as a consulting physician, were so great that many were surprised when Ryle left the broad highway of medicine in 1935 to accept the regius chair of physic at Cambridge. It was less of a surprise to those who were familiar with his growing preoccupation with social problems and with the need for a reorientation of medical education and practice. The attempt to start a new clinical school at Cambridge was frustrated by the war. In addition, it seems probable that both at Cambridge and at Oxford the establishment of a university hospital would have required greater expenditure and a sharper break with the past than most people were prepared to support.

During the war he returned to Guy's, which was then depleted of staff and in a heavily bombed area. His experiences deepened his interest in medicine as a community problem, and he gladly accepted the invitation to take charge of the newly founded Institute of Social Medicine in Oxford in 1943. Here he found a congenial field for his talents, and the next six years were extremely fruitful. He hammered out his conceptions of social medicine, as both a service and a scientific discipline, in a number of lectures which were collected and published in 1948 under the title *Changing Disciplines.* Oxford became a centre of pilgrimage for students of social medicine, and Ryle visited India, America, and South Africa to disseminate his ideas. His departure from the chair of social medicine and from Oxford makes a gap that will not easily be filled. Nevertheless, one of his constant aims has been to attract good people into social medicine and he leaves a strong team behind him. His pen is not likely to be idle in his retirement in his home beneath the S
downs, where the trackways, the circles of beech
and the evidences of ancient man have so often br
him " the still, sad music of humanity."

FINDING BEDS IN LIVERPOOL

THE Liverpool Regional Hospital Board re
that on completing its first year's work last Septe
the Liverpool Emergency Bed Bureau had rec
9260 requests for admission. Accommodation was f
in 8923 cases, though in 430 it was not accepted.
remaining 337 (3½%) are reported as " failures,'
35 of the patients were admitted at a later date.
" failures " are detailed at some length, and it is no
able that some of them at least are barely disting
able from chronic waiting-list cases—e.g., chronic h
failure and senility. As might have been expe
about two-thirds of the " failures " occurred in
first three months of the year.

The bureau has admitted to 73 hospitals, including
Liverpool teaching hospitals, and has clearly follo
the spirit of the National Health Service in not allov
management-committee or regional-board boundarie
be any bar to the movement of patients. From
steady increase in the use made of the bureau i
evident that it has earned a high reputation and
be extensively used this winter.

CONSULTANT SERVICES

SIX months before the National Health Service c
into being the regional hospital boards received from
Ministry of Health a long memorandum on the deve
ment of specialist services.[1] This document has been
useful during the past two years, and now, with a
minor alterations, it has been officially issued to
public.[2] Pointing out that the distribution of consulta
has been haphazard and uneven, it rightly says that
regional planning now possible will continue to be
of the most important functions of the boards. " Dis
bution can be improved by the creation of new sala
posts, part or whole time, beginning first in those a
where the need is greatest." The deficiency in numb
however, can be made good only gradually, for " i
imperative to avoid the mistake of expanding consult
staffs by recruiting men and women with inadequ
training and experience." Under the headings of vari
specialties the memorandum discusses the requireme
for a hypothetical average hospital district with
population of about 100,000–120,000. The main probl
of the regional board, it is suggested, will be to integr
the consultant services of the hospital centres with th
of the regional centre—which includes the teach
hospital. It seems best that, apart from plastic surge
neurosurgery, thoracic surgery, and radiotherapy,
services of a complete range of consultants should
available at each hospital centre, and that these co
sultants should be fully responsible for the hospi
treatment of its population.

> " Under such conditions, linkage between the Regio
> and Hospital Centres would be maintained by recognisi
> all the consultants throughout the Region as members
> one team. Members of the staffs of Hospital Centres shou
> be given the opportunity to take temporary duty
> hospitals at the Regional Centre, and some grades
> medical staff in the Regional Centre should similarly ha
> opportunities of doing temporary duty in a Hospi
> Centre."

The memorandum concludes with useful appendic
showing, for each region, the population, the number
hospitals, and the number of beds.

Sir ARCHIBALD GRAY has been appointed to t
General Medical Council as representative of the Unive
sity of London in place of the late Sir Herbert Eason.

AN OUTPATIENTS' CLUB

W. A. Bourne
M.D. Camb., F.R.C.P.
PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON

This paper describes an attempt, on a small scale, to solve the problem of the long-term outpatient. Even a partial solution may go some way to solve the still more harassing problem of accommodation for long-stay inpatients. The latter have forced themselves on our attention more objectively since the fusion of all hospitals into a general service. Professional and lay people, accustomed to working under the voluntary-hospital system, have been shocked to discover the great numbers of chronic sick never dealt with under that system, who have now become part of their responsibility. Departments and specialties, which had hoped that extension to other hospitals would mean increased opportunities to treat acute and urgent illness, find instead that many of their beds are occupied by elderly, paralytic, rheumatic, cardiac, or otherwise incapacitated patients. This rather sudden awareness of the facts, and the knowledge that our population is progressively ageing, has led to serious consideration of the care of old people and of the chronic sick, especially from the standpoint of prevention and rehabilitation. As part of this problem, the management of old age and chronic illness in outpatient departments assumes importance.

THE PATIENTS

Firstly, old age. Between normal old people on the one hand, and the incapacitated inmates of chronic blocks on the other, there is a large group of the elderly who attend outpatient departments for lengthy periods. An analysis of 1028 outpatients whom I saw for the first time during 1948–49 gave the following figures:

Age-group	*Number of patients*	*Percentage*
0–15	19	1·8
16–25	61	5·9
26–35	117	11·4
36–45	157	15·3
46–55	233	22·7
56–65	223	21·7
66–75	181	17·6
76–85	36	3·5
86–95	1	0·1
Total	1028	100·0

It will be seen that 21·2% of these new patients were over sixty-five and had reached what is often considered old age; and they would probably need treatment differing in kind and duration from what is applicable to younger people.

Secondly, chronic ill health. There is a group which attends hospital over long periods suffering from chronic incapacitating diseases. Of these, rheumatism is an example. Records were kept of patients who attended a rheumatic clinic under my charge during 1946–48. The total was 440, of whom 58, or 13·2%, attended the clinic—as distinct from the physiotherapy department—for six months or more: an appreciable number had attended for many years.

PHYSIC OR FELLOWSHIP?

A notable—indeed inescapable—feature of these outpatient departments was the constant and amiable chatter among the patients while they were waiting to see the doctor. Indeed, the brief interview in his room often seemed to play only a minor part in the morning's visit. Frank consideration led me to the regretful conclusion that the benefits of treatment were often not detectable by objective methods of diagnosis; but, though the physical condition and the wording of complaints remained unchanged over many years, the patients believed that they derived great benefit from their attendances.

These observations led to the idea that a few of these patients should be allowed to visit hospital without seeing a doctor at all. Through the enthusiasm and all-round ability of the staff of the Latilla physiotherapy department at the Royal Sussex County Hospital, Brighton, a Rheumatic Club was accordingly formed, and this has held regular fortnightly meetings for two years. It does not, in fact, consist of rheumatic patients only; any one with a chronic incapacitating disease can become a member. As it is easier for most patients to make a day-time visit, meetings are held during the working day of the department. To minimise interference with the routine work, a small room is all that is set aside. The number of members has thus had to be restricted to about 15, though many more would be glad to join and there is practically a waiting-list.

Among these chronic invalids the atmosphere of great cheerfulness supports the original conception that a great deal of the benefit they derived from attendance at outpatients was from human fellowship rather than from the ritual medical advice and bottle of physic. They are unanimous that they "look forward to the meetings," which "make a break" and are "jolly good treatment." Some of the members never leave their homes except for their fortnightly visit, which provides the only fresh faces and conversations they have.

I am now convinced that the formation of such "clubs" should be an important part of the work of our health service. In the past quite a number of people have made a considerable proportion of their social contacts by visiting an outpatient department. The qualification has been the prescription form for a bottle of medicine or a course of physiotherapy. To refuse this treatment has been to cut them off from their contacts; but to allow it from kindness of heart has been to perpetuate an unsatisfactory attitude of mind.

Hospitals should accept, as part of their function, the duty to reable and encourage these patients through social activities, without the intervention of orthodox medical therapy. Later this work should no doubt be transferred outside the hospital walls: we hope, for example, to develop connexions with a local old people's club. Hospitals have, however, advantages which make them the most suitable meeting-place to begin with, and, if medical aspects are not allowed to obtrude, the development of healthy independence is not interrupted. It should be remembered that the object of every health service is to make hospitals obsolete.

One of the advantages which the hospital possesses is transport. With W.V.S., hospital service, and ambulance cars at its disposal, invalids can be taken to hospital more easily than to a club elsewhere. Other advantages are the provision of materials and reading matter. The Red Cross welfare officer can offer wool, silks, and materials for embroidery, rugmaking, and the like at cost prices. Through the Red Cross and St. John libraries books are provided and changed at each visit. With these aids the Red Cross and St. John workers attached to the hospital have been able to develop a spirit of independence in members. At first it was found helpful to have entertainments, lectures, and community singing, and these are still welcomed from time to time: but the essential purpose is to let members interest and amuse themselves, and once this is achieved outside interests are not wanted.

Gravely incapacitated patients are given suitable occupational therapy; those who are more active knit, sew, make rugs, or do other handwork, most of which can be sold. Once a year, usually at Christmas, an At Home and exhibition of work is held, and in the summer a tea-party for the club is held at the home of the original organiser. These are now the formal activities. The essential benefit of the work depends however, on its informality. Tea, cakes, and cigarettes are provided, and the meeting is spent in buying materials, examining patterns, comparing jumpers, mats, and suchlike completed in the past fortnight, and changing library books—all among a babble of conversation. It is better to mix the sexes.

At first financial support came from voluntary donations. At another hospital, the house committee has allotted funds to start a similar club. Once the work is under way, the goods can be sold at a profit. The members also spontaneously suggested a subscription, and they now have their own treasurer, who collects a shilling a month from each. This money is used to buy cakes and cigarettes from friendly tradesmen nearby. With some help from hospital supplies, the club is, in effect, self-supporting.

On this groundwork, other services, such as advice from the almoner when money or other difficulties arise, are provided as needed. The principle is, however, extremely simple—to pick from the population of outpatient departments the crippled, lonely, and ageing, and help to keep them mobile, active, and purposeful, to find them friends, and to show them that they are not peculiar isolated cases and that other people who are equally handicapped can do things, be real persons, and find life worth while. Preventive treatment of chronic disease and of the physical and emotional incapacities of old age is a vital necessity if the burden on chronic bed accommodation is to be kept within bounds. Outpatient clubs can do much to ease this burden.

Acknowledgment must be made to those who put this idea into practice: Miss K. Ward, late sister in charge of the Latilla department; her successor, Miss L. B. Martin; Miss Wildey, occupational therapist, who brought to the work the spirit of St. Dunstan's; the British Red Cross and St. John; and Dr. R. W. Windle, for finding space in his busy department.

ELECTION CANDIDATES

THE lists of candidates include the names of the following medical men and women:

LONDON BOROUGHS

Fulham West.—*Edith Summerskill, M.R.C.S. (Lab). W. J. O'Donovan, O.B.E., M.D. Lond. (C).

Holborn and St. Pancras South.—*S. W. Jeger, M.R.C.S. (Lab).

PROVINCES

Barking.—*Somerville Hastings, F.R.C.S. (Lab).
Bath.—Bruce-Cardew, L.M.S.S.A. (Lab).
Batley and Morley.—*A. D. D. Broughton, M.B. Camb. (Lab).
Cheshire, Crewe.—J. R. T. Turner, M.R.C.S. (C).
Cheshire, Northwick.—W. N. Leak, M.D. Camb. (L).
Gloucestershire, West.—W. H. Tandy, F.R.C.S. (L).
Gosport and Fareham.—R. F. B. Bennett, L.M.S.S.A. (C).
Hertfordshire, Barnet.—*Stephen Taylor, M.D. Lond. (Lab).
Kent, Tonbridge.—E. St. J. Lyburn, M.B. Dubl. (Ind).
Luton.—Charles Hill, M.D. Camb. (L and C).
Preston.—*Samuel Segal, M.R.C.S. (Lab).
Stoke-on-Trent, Central.—*Barnet Stross, M.B. Leeds (Lab).
Surrey, Carshalton.—Sydney Sharman, M.B. Glasg. (Lab).
Warrington.—*H. B. Morgan, M.D. Glasg. (Lab).
Willesden, West.—Genevieve Rewcastle, O.B.E., M.B. N.U.I. (C).
Yorkshire, West Riding, Ripon.—*Lieut.-Colonel Malcolm Stoddart-Scott, M.D. Leeds (C).

WALES

Cardiff, South-East.—J. J. Hayward, M.R.C.S. (C).
Cardigan.—G. S. R. Little, M.R.C.S. (C).

SCOTLAND

Glasgow, Kelvingrove.—*Walter Elliot, P.C., M.C., M.B. Glasg. (C).
Lanark, Motherwell.—R. D. McIntyre, M.B. Edin. (Scot Nat).
Orkney and Zetland.—*Sir Basil Neven-Spence, M.D. Edin. (C).

C, Conservative. Ind, Independent. Lab, Labour. L, Liberal. Scot Nat, Scottish Nationalist.

Public Health

BACTERIAL CONTAMINATION OF AIR IN UNDERGROUND TRAINS

R. E. O. WILLIAMS
M.D., B.Sc., Lond.

ANN HIRCH
B.Sc. Lond.

OF THE AIR HYGIENE UNIT, CENTRAL PUBLIC HEALTH LABORATORY, COLINDALE, LONDON

With an appendix

SLIT-SAMPLER FOR LONG-PERIOD SAMPLING OF AIR FOR BACTERIA

O. M. LIDWELL
D.Phil. Oxfd

OF THE MEDICAL RESEARCH COUNCIL GROUP FOR RESEARCH IN INDUSTRIAL PHYSIOLOGY

SURVEYS of the bacterial flora of the air in underground railways were carried out by Andrewes (1902) and Forbes (1924) in London, and by Soper (1908) and Buchbinder et al. (1938) in New York. Air-sampling apparatus has been greatly improved in the last few years, and it seemed desirable to include the cars of underground railway trains in a survey that we have been making of the bacterial contamination of the air of occupied places.

METHODS

Samples of air were collected on six double journeys across London during the evening rush-hour: (I) three from Golders Green via Charing Cross to Kennington and back (in two cases the return journey included the line between Golders Green and Edgware, where the trains are above ground); and (II) three from Golders Green via Bank to Morden and back. The car was never crowded on the outward half of route I but was usually full on the first part of the return-journey (minutes 40–60 in fig. 1), after which the passengers left in small numbers at each stop. On route II the car was crowded for the second half of the outward journey (minutes 25–50 in fig. 1), but not on the return.

The car in which the observations were made was of the modern underground-railway type, open in its full length with seats on both sides; it had one pair of single and two pairs of double doors on each side, and all the doors on one side were opened at each station. We used the central car of the train, and this car has a driving cab at one end cut off from the body of the car except for a window about 12 inches high by 6 inches wide. 5 feet from the floor. The sampler, which is described in the appendix, was set up in the cab, and a hood, which fitted tightly over the slits of the sampler, projected into the window; air was drawn through the hood by a small fan, and the sampler took air from this stream (fig. 2). Observers were stationed at each end of the car to keep notes of the number of passengers, time of entering and leaving stations, and the time that windows were opened or closed. All the samples were taken in the same car, which was a "non-smoker." On route I samples were taken in September, November, and December, 1947, and on route II in January, March, and July, 1948.

One of the two slits of the sampler passed 0·33 c. ft. of air per minute (at the working pressure of 12 in. water-gauge), and the particles from this slit impinged on nutrient agar containing 5% horse-serum. The other slit passed 1·3 c. ft. per minute, and the particles from it were collected on a selective medium for streptococci (Williams and Hirch 1949); a *Strep. viridans* count has been proposed as an index of pollution of air from the respiratory tract (Gordon 1902–03, Wells et al. 1941), and we wished to include such an index in our survey. The colonies developing on the serum-agar were counted fter twenty-four hours' incubation at 37°C; the selective lates were examined after forty hours' incubation, nd, after counting, films were made in nigrosin of a andom sample of the colonies and examined microcopically to recognise the streptococci. The streptoccal count reported is therefore based on the total umber of streptococci, regardless of the hæmolysis that hey would produce on a blood-agar medium.

RESULTS

The counts of total viable bacteria for the three runs on each route agreed sufficiently closely to justify our reporting only the average, and the charts (fig. 1) show three-minute moving averages of the counts on each run; moving averages were adopted to smooth out minor fluctuations in the count, which were often accentuated by the irregular movement of the sampler caused by the jolting of the train. Our estimate of the number of passengers present was necessarily an approximation once the car was full; 110 was taken as a maximum.

Two facts are outstanding in the chart. First, the general bacterial count never reached a very high figure —in fact, the highest count obtained in any one-minute period was 170 colonies per c. ft. and the averages over the three runs on each of the two routes were 47 and 32 colonies per c. ft. The streptococcal counts were also extremely low: 0·33 per c. ft. and 0·22 per c. ft. (with a single peak up to 2·9 per c. ft. in one minute). Secondly, the count rose steeply when people entered the car, and tended to settle rapidly even while the car was still full; and a relatively small rise in the number of passengers, to about 20, caused as large a rise in the count as did the entrance of 50–100 *people*. The streptococcal count followed the same general pattern.

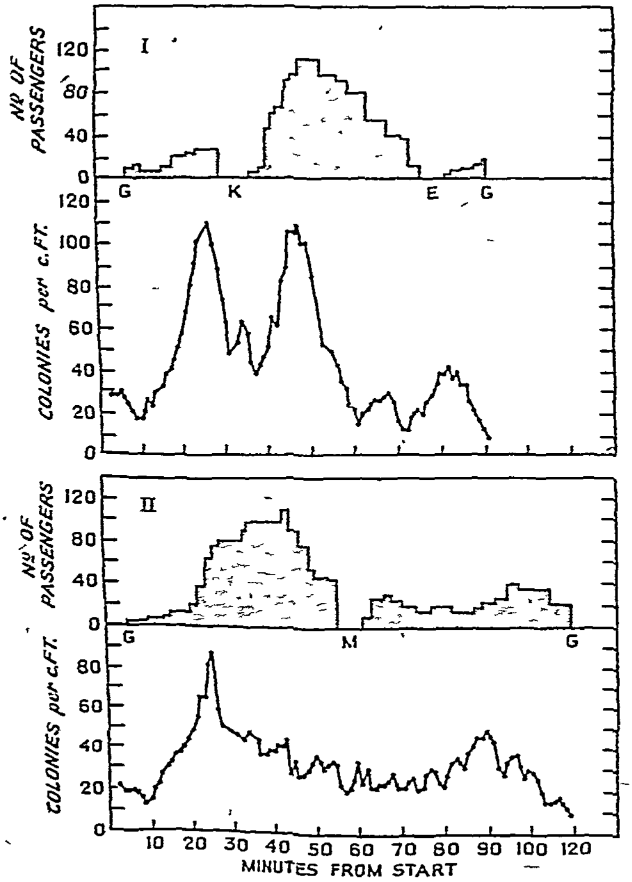

Fig. 1—Three-minute moving averages of colony count on serum-agar plates, and approximate number of passengers in the car: I, Golders Green (G) to Kennington (K) via Charing Cross, and back to Edgware (E), and Golders Green; II, Golders Green (G) to Morden (M) via Bank, and back. In each case the curve represents the mean values from three journeys on the route.

On each journey temperature and humidity readings were taken at about ten-minute intervals on the excess air escaping from the sampler hood. There was no systematic change in the relative humidity, which varied from 39 to 67% on route I and from 31 to 65% on route II. There was, however, a steady rise in temperature during the runs, generally about 12°F, the limits being 51–79°F on route I and 61–82°F on route II.

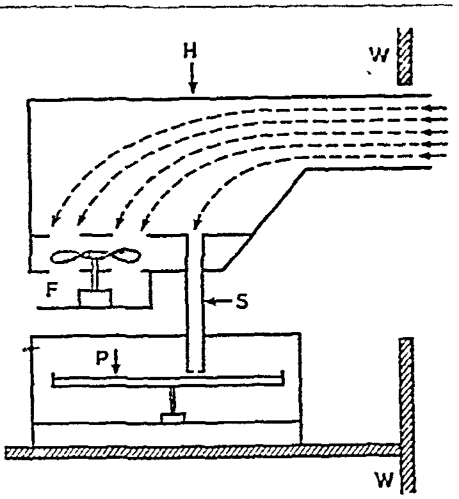

Fig. 2—Diagrammatic section of sampler and hood: W, wall between cab and body of car; H, thin metal hood; F, fan sucking air through hood; S, slit tube of sampler; P, petri dish in sampler.

DISCUSSION

In view of the number of people on these trains during the rush period the counts obtained were surprisingly low compared with those observed in other occupied places. For example, we have observed a mean count *of 80–100 colonies per c. ft. in a large number of observations* in elementary-school classrooms and of 76 per c. ft. in some public offices (unpublished observations.)

It is impossible to make strict comparisons with previous work in underground trains, owing to fundamental differences in sampling and bacteriological technique. Forbes (1924), who incubated his plates for six days at 37°C, obtained an average count of 112 colonies per c. ft. for all the six railways. Andrewes (1902) gave 40 per c. ft. as the mean count for his plates incubated at 37°C. Soper's (1908) observations are not comparable with those considered above, since he only used settling-plates in the cars of the subway. Buchbinder et al. (1938) recorded an average of 0·1 streptococci per c. ft. of air in the New York subway cars, but their method of recognising streptococci differed materially from ours.

Once the passengers have filled the centre of the car, there tends to be relatively little movement for some time, and the rapid drop in count observed may be due to removal of the bacteria by ventilation and settling. coupled with a reduction in their dispersal; we have not found any other explanation for this fall. There does not seem to have been any association between the drop in count and the opening of windows; and since the same fall occurred on both the Charing Cross and the City lines, it seems doubtful if it had any connexion with the arrangement of tunnel-ventilating plants, which supply fresh air at some stations and extract the vitiated air at others. The steep rise in count with the entry of a few passengers might be expected if, as seems likely, most of the bacteria in the air of these trains are liberated from the clothing of the occupants and from the upholstery, since there is more opportunity for movement when the number of people is small. Forbes (1924) made a similar observation. The sampler had, of necessity, to be at one end of the car, and we do not know whether the bacterial count is the same there as in the centre or by the side doors.

It seems clear that there was no massive accumulation of airborne bacteria in these trains, and the rapidity with which the count fell from its peaks suggests that there can be but little risk of any persistent contamination of the air with pathogenic bacteria. The small number of streptococci isolated from the air indicates, too, that there was not on these occasions massive pollution from respiratory sources; and it is true that in underground trains the activities that produce most streptococcal droplet nuclei—sneezing and coughing—are not very common, and there is not even much talking. There must nevertheless still be a risk of transfer of respiratory infection, between passengers standing crowded together, by the more direct routes—by mouth droplets that are too large to remain airborne, and by particles from handkerchiefs (Dumbell et al. 1948). These risks cannot be satisfactorily estimated by examining samples of air withdrawn from the car in the way that we have done.

SUMMARY

A bacteriological examination of the air of underground trains was made during six double runs across London at the evening rush period.

The average count of aerobic bacteria for three journeys from Golders Green to Kennington via Charing Cross was 47 colonies per c. ft. and from Golders Green via Bank to Morden 32 per c. ft.

The highest count in any one-minute period was 170 colonies per c. ft.

The entry of even a few passengers into the car raised the number of bacteria recovered from the air considerably, but thereafter the count of airborne bacteria fell even before many passengers had left.

The mean counts of total (α, β, and non-hæmolytic) streptococci on the two routes were 0·33 and 0·22 per c. ft.

This work could not have been done without considerable assistance from the London Transport Executive, and we are very grateful to Dr. L. G. Norman, Mr. Bradley, and other members of the staff of the railways for their constant help; and to the Executive for permission to publish these results.

Slit Sampler for Long-period Sampling of Air for Bacteria

(DR. O. M. LIDWELL)

This sampler is a development of the slit sampler described by Bourdillon et al. (1941, 1948). Two 6 in. petri dishes are mounted side by side in the airtight box which comprises the body of the sampler. Air is exhausted from this box so that the air to be sampled enters through two tubes passing through the roof of the box. These tubes are closed at their lower ends except for a diametral slit in each. The height of the slits, each 0·5 in. long, can be adjusted so that their lower edges lie 2 mm. above, and parallel to, the agar surfaces of the petri plates, this being the greatest permissible separation for efficient collection of the smallest bacteria-carrying particles. The sampled air impinges on the agar, depositing any bacteria-carrying particles. The slits are so oriented that, if prolonged, the line would pass through the axes of rotation of the petri dishes. The petri plates rotate together about their centres and at the same time move laterally, parallel to the slits, travelling $^{5}/_{8}$ in. for each revolution of the plates. The bacteria-carrying particles are thus deposited along a spiral track with a pitch of $^{5}/_{8}$ in. and $^{1}/_{8}$ in. separation between successive turns. This track has a radius, at its centre, of $2^{1}/_{4}$ in. at the start of a sample, dropping to 1 in. at the end of the two turns which comprise the completed motion. The total length of the track is about 20 in., and about 45% of the surface of a petri dish with an internal diameter of $5^{1}/_{4}$ in. is usefully employed (fig. 3).

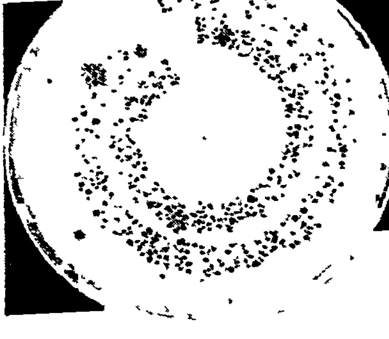

Fig. 3—Serum-agar plate exposed in spiral sampler for 1 hour and incubated for 24 hours at 37°C. Bacterial colonies lie on spiral track 0·5 in. wide. Gap in trace was produced by turning off suction for 3 minutes in middle of sample

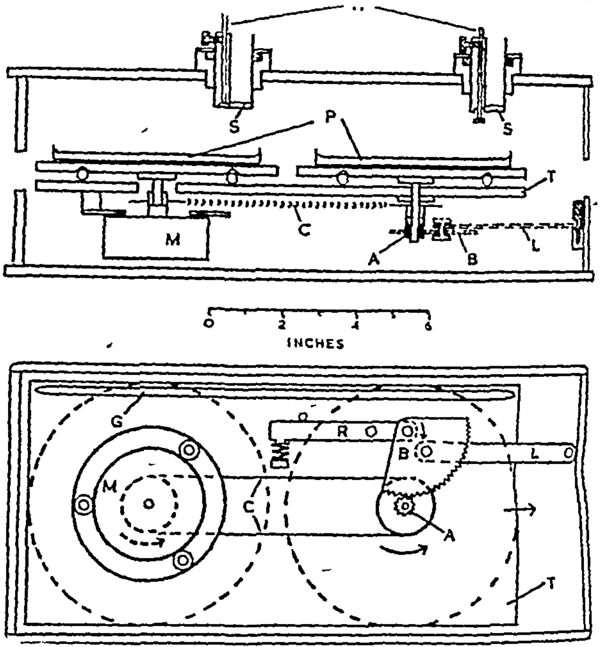

Fig. 4—Diagram of sampler: above, vertical section through middle of base, with lid raised 1 in.; below, underside of trolley, showing link mechanism; A, pinion, 19 teeth No. 38DP; B, sector, 44 teeth; C, chain drive; H, float height indicator for adjusting slit-agar separation; S, slit; L, link; M, synchronous motor; P, 6 in. petri plates; R, release, operated from above, for resetting trolley to starting position; T, trolley running on balls in lateral grooves and guide groove G. Broken lines show detail obscured by overlying parts or out of plane of diagram. Arrows indicate direction of motion during sampling.

With this type of sampler it is possible to obtain a relatively long length of track on a petri dish of convenient size, a feature which has proved very useful in field investigations where a continuous assessment of the aerial contamination over a period is often preferable to an intermittent series of short samples. The incorporation of two plates on to which simultaneous samples can be taken at different rates of air flow is a further advantage when pathogens or indicator organisms are sought with selective media. The mechanical details, including sampling-rates and duration of sample, are susceptible of considerable variation. For the present investigation the sampling slits, cut in a plate $^{1}/_{8}$ in. thick, were $^{30}/_{1000}$ in. and $^{10}/_{1000}$ in. wide, passing 1·3 and 0·33 c. ft. of air a minute at the working pressure of 12 in. of water, while the plates were arranged to rotate once in 30 minutes, giving a total sampling-time of an hour.

Fig. 4 illustrates some aspects of the construction; the details shown relate to later improved models and differ in some respects from those of the sampler used in the investigation described above. Particular points are:

(1) *Driving Power.*—The original model was driven by an alarm-clock movement. This proved too weak for the purpose and has been superseded by a synchronous electric motor (Venner type M2T). When A.C. mains are not available, this can be driven off dry batteries through a 50-cycle vibrator,

sing either a step-up transformer or, preferably, a centre-
ped low-resistance motor coil (500 turns of no. 30 S.W.G
melled copper wire is suitable for use in conjunction with
e 0800 cycle-type batteries).

2) *Slit Tube Bearings.*—So long as the tubes fitted their
porting collars reasonably well, no gasket or sealing was
essary, and leakage of air was negligible, especially if
tubes were lightly greased. Felt washers were incor-
ated to maintain this lubrication.

3) *Lateral Motion.*—A double rack-and-pinion system was
d in the earlier models but proved rather complex and
le to considerable backlash. The much simpler and more
ust link action illustrated does not produce a true spiral
ck, but the deviations are insignificant in practice.

Up Pirquet, Down Mantoux!

THE now historic tuberculin-testing and B.C.G. vaccina-
on of tuberculin-negative probationer nurses at the
slo City Hospital, Ullevaal, which began in 1926, has
inged on the Pirquet test with old tuberculin and without
drenaline. Dr. J. Heimbeck, the author of this under-
king, who has brought the story of it up to date,[1]
as never been a wild-eyed devotee of the Pirquet test,
ut he has stuck to it because he could find no better.
a his hands it has been quite useful in distinguishing
hose infected from those not infected with the tubercle
acillus, and in indicating the latter as suitable for
.C.G. vaccination. Once positive, the test is always
ositive except occasionally in the old and in some
everely ill people. All the 1247 Pirquet-positive persons
n Oslo whose Pirquet-testing was repeated once or
ftener, were found to be again Pirquet-positive, many
fter an interval of several years. Heimbeck recalls
hat in Denmark Sigrid Holm showed that 30% of
.243 people who were originally Mantoux-positive
ecame Mantoux-negative after a certain time. Heimbeck
rites: "There is therefore only one possible explanation
f all the revertors with the Mantoux test: it is that
n a great number of cases Mantoux gives a false reaction
r one which is interpreted wrongly, and Mantoux is
herefore an unreliable test on which to base B.C.G.
accination." With reproachful surprise Heimbeck
efers to instructions on tuberculin-testing and B.C.G.
vaccination contained in a pamphlet published by the International Tuberculosis Campaign. Here an account is given of the Mantoux and Moro tuberculin tests, whereas nothing is said about the Pirquet test "on which" as Heimbeck remarks, "the whole of B.C.G. vaccination is founded." Heimbeck asks—evidently with little hope of a satisfactory answer—what investigations have been carried out with the Mantoux, the Moro, the adrenaline-Pirquet, or other tests which can show as conclusive results as those he has obtained in his Ullevaal nurses with the Pirquet test using old tuberculin and no adrenaline.

Control of Air Traffic

For the health control of air traffic the five countries of Western Union—Belgium, France, Luxembourg, the Netherlands, and the United Kingdom—are on Feb. 1 to become one single area, which will be known as the "excepted area." The effect of this agreement is as follows:

1. An aircraft beginning its flight anywhere within the excepted area will not normally be subject to health control on arrival anywhere else within the area. This does away with the aircraft declaration of health (by the commander of the aircraft) and with the personal declarations of origin and health by the passengers.
2. An aircraft, and its passengers, which begins its flight outside the area will be subjected to health control within the area only at the place where it first touches down.

The excepted area may be restricted by the ministers of health, to exclude temporarily any of the member countries, or parts of them, in which there is an epidemic.

The new scheme is the result of a system devised by the Public Health Committee of the Brussels Treaty Organisation. In each of the five countries passengers landing from an "infected" area will receive the same kind of "warning" postcard to hand to their doctor if they fall ill shortly after landing.

Births and Fertility in 1944

The Registrar-General's Statistical Review for 1944[1] completes the war-time series of volumes of civil tables. It records a slight rise in the birth and marriage rates as compared with the year 1913 and a continuation of the downward trend in the stillbirth-rate.

Births.—There were 751,478 live births in 1944, representing a rate of 17·7 per 1000 total population. This was an increase of 1·5 per 1000 over the previous year. Illegitimate live births numbered 55,173, compared with 43,709 in the previous year (7·3 and 6·4% of the total live births respectively). There were 21,306 stillbirths, representing a rate of 28 per 1000 live and still births, compared with 21,262 and a rate of 30 per 1000 in the previous year. This improvement has been maintained in later years, the provisional rate in 1948 being 23 per 1000.

Fertility.—43·2% of the legitimate confinements during 1944 were to mothers with no surviving previous children; 29·8% to mothers with one surviving previous child; and 13·4% to mothers with two. There were 9604 confinements which resulted in multiple births, of which 9520 were twin, 80 triplet, and 4 quadruplet maternities. All the quadruplets were liveborn.

Second Quarter of 1949 in Eire

The Registrar-General of Eire[2] reports that in the June quarter of 1949 the birth-rate was 22·2 per 1000 of the estimated population—1·8 less than that in the second quarter of 1948. Illegitimate births amounted to 3·4% of the total births recorded. Deaths were at an annual rate of 13·3 per 1000, which was 0·7 above the rate for the second quarter of the preceding year. The death-rate for all forms of tuberculosis was 1·0 per 1000—pulmonary 0·8 and other forms 0·2. The infant-mortality rate was 50 per 1000 births registered, compared with 46 in the June quarter of 1948.

1948 Death-rate in the U.S.A.

In the U.S.A. the death-rate in 1948 was the lowest ever recorded. Figures published by the Public Health Service's National Office of Vital Statistics show that the crude rate was 9·9 per 1000 population—2% below the rate of 10·1 for 1947 and 1% below the 1946 rate, the previous low record. Deaths from all forms of tuberculosis amounted to 30 per 100,000 of the population, compared with 33·5 in 1947.

London's Health in 1949

Provisional statistics for London in 1949 are given in a preliminary report by Sir Allen Daley, county medical officer of health. The infant-mortality rate (28 per 1000 live births) and the neonatal-mortality rate (16·5 per 1000 live births) were the lowest ever recorded. The over-all death-rate was 11·9 and the birth-rate 16·9 per 1000 population. The maternal-mortality rate was 0·78 per 1000 live and still births: during the year not a single death from puerperal sepsis was registered.

NEONATAL MORTALITY.—In England and Wales during 1948 the rate was 19·72 per 1000 related live births (males 22·20, females 17·08). This is reported in the Registrar-General's return for the week ended Jan. 7.

In England Now

A Running Commentary by Peripatetic Correspondents

I HAVE hit on a new method of stating the prognosis of chronic dermatoses, and one which will not depress the patient who gets a sight of his case-notes. It came to me while I was taking the pulse of a fibrillating old crone in a Gloucestershire cottage. To while away the minute I admired some papillomatous remains on her wrist. "Ah," said she, "them's the remains of My Skin Disease. It took nigh on a hunderdweight of ointment to cure tha'. Th' old doctor brought it in fower ounce pots at a time and I counted un." There it was in a nutshell and so simple. Subheadings may be added according to colour or constituents of the ointment we think will be needed. Then when we write "Eczema, arm, 28 lb. pasta zinci co." it will add a new interest to our chronic cases to see whether we can keep to our estimate.

* * *

The Bostonian had left Grand Central Terminal only five minutes before, and I was enjoying the comfort and novelty of modern railroad transport in America, when the sombre voice of the conductor on the loudspeaker disturbed my reverie: "Will everyone please pay attention now. If there is a doctor on this train will he please meet me in the second car. There is a passenger been taken seriously ill."

I was in no doubt what to do; it was true that I was under a full-time contract with Mr. Bevan and I had agreed not to indulge in private practice, but it would surely be expected of me to help in an emergency, so I resolved to leap forward from my comfortable blue upholstered seat and proudly introduce myself: "British Medicine—at your service!" So, swallowing my natural diffidence and the last mouthful of a Hershey almond bar, I proceeded up through the air-conditioned coach, praying that the emergency would not call for any obstetrical skill. My fellow passengers displayed intense interest and smiled at me encouragingly. I could see that they were proud of their fellow passenger. "Hope you find your patient not too bad, doctor," said one of them. A few yards up the same beautiful steel coach another said, "Your patient is right here, doc." and just opposite sat an agitated old lady. Beside her in tears and wringing her hands was her anxious bespectacled daughter. A moment or two later our company had grown to include the conductor, a couple of trainmen, the "ham sandwich, turkey sandwich, milk, peanuts, and ice-cold Coca-cola" vendor, a sick-bay attendant from the American navy, and a priest. Having hinted to the last-named that his presence was therapeutically unwise, I sat down beside my patient and asked her destination. When she replied "Providence" I was for recalling the priest had not the daughter chipped in, "Of course, doctor, we don't need to go to Providence, we can get off at New Haven; don't you think it would be a good thing? We could continue our journey tomorrow when mother is more settled."

I was confused at having momentarily forgotten the existence of Rhode Island and its capital but once more reassured the willing priest that this was, after all, a job for me. "Are you a real doctor?" asked the old lady, as I held her wrist, noting a healthy pulse albeit a tortuous artery. I assured her that not only was I a real doctor but that I had just that morning arrived from England and that she was my first transatlantic patient. "Do you mean to tell me," she added, "that you are one of those Socialised physicians?" "Yes," I said. "Then don't they provide you with a bag?" she asked, with obvious concern. I was about to explain that as my specialty involved the conduct of autopsies I seldom carried equipment around with me, when I noticed a change in my patient evidently brought about by her interest in England. She was no longer agitated, her hyperventilating tendency had subsided, and she no longer complained of the pain which had been "all over" her chest and abdomen.

My spot diagnosis of "anxiety neurosis" was evidently correct, and I knew that if I could eradicate the exciting cause of the attack—the daughter—we should all finish our journey in peace. "Don't patients any longer have to pay their doctors over there?" she asked. "No,
replied, "the service is entirely free," and then, correcti
myself, I explained how it was in fact so expensive th
people were determined to get their money's worth c
of it. "My mother is very interested," said the daught
"for she has paid many doctors bills' in her 87 years of lif

The potential drama had now resolved itself into
informal and amicable debate, in which neighbouri
travellers freely took part, on the merits and disadva
tages of State medicine, when the conductor took
aside and suggested quite rightly the exhibition of
placebo. We retired together to the galley in the adjoini
grill car, and with the aid of the train-crew's first-aid
and a veritable dispensary in the daughter's hold-a
we concocted a sedative which seemed likely to
effective so long as the daughter was kept occupied.
advised continuing the journey to Providence.

Regular bulletins were brought to me in the grill c
where I studied my first American menu with eag
anticipation. The fashionable young sophomore opposi
leant over the remains of a sizzling Welsh rarebit wit
crab salad to exclaim, "I'm right glad your patient i
better, doctor; it sure is a wonnerful profession."
noticed that her attractively set toque remained undi
turbed as she drained her chocolate milk-shake. Tl
train-man came to find me and explained that in purs
ance with regulations they had decided to call in tl
company's disaster squad at New Haven. I realised no
that they no longer had confidence in me because I h
no bag. The chicken pie still tasted good but I felt hu

The railroad team was an impressive turnout; ho
could I compete with two ambulance drivers, three bag
and a stethoscope? The company's doctor rapid
confirmed my diagnosis and brewed a sedative whi
quietened both ladies for the rest of the journey.

On our arrival at Providence I was awakened by t
daughter. "You sure were wonnerful to mother and
want to pay your fee," she said, fumbling with a t
dollar bill in the upper reaches of her hand-bag.
explained that the humble services I had rendered cou
be regarded as an extension of the National Healt
Service Act, 1946. She thanked me cordially, wished n
an enjoyable visit to the States, and remarked that sl
hoped they would never nationalise their doctors
America because they liked to pay for their servic
individually. I did not think that this view had bee
engendered in her by my doctoring, but I resolved t
carry my pyjamas and toothbrush for the rest of m
stay in a doctor's bag.

My peripatetic friend last week, who encountere
Bessy at Christmas, had a bit of bad luck; but at leas
he can console himself with the thought that he wa
witnessing the effects of a rare bit of good luck on poo
old Bessy. Speaking as an ex-problem-child (wit
none of Bessy's provocation) I congratulate her warmly
adenoids and all, for being able to keep up her spirit
in an atmosphere of powerful dislike. She may not b
much cop, but lord! you should have seen me in my
heyday. At my most obnoxious I was frightened out o
my wits by the vast enmity I provoked. I suppose i
Bessy had had an eye or a leg missing she would have
been better tolerated—and possibly more tolerable.
But the poor girl has nothing to show the world but her
adenoids.

* * *

At a recent meeting of my club—the M.R.C.P. Faileds—the new methods of conducting the examination were generally applauded. In our view the presence of a younger man at the vivas helps to give confidence, and with two examiners a correct answer is unlikely to be misinterpreted. But there were one or two criticisms. This is an expensive club, probably one of the most expensive in London, with an imposing entrance, and it seems a little unfair that the paying members have to go in by the tradesmen's door through a corridor where the 600 or so of us form a scrum that makes the Rugby Cup Final dwindle into insignificance. Can it be too that the distinguished Censors have been so long away from physiology as to forget the causes of frequency? Four stalls per 600 men under stress seems a little thin, and a feeling of urgency is not (repeat NOT) conducive to clear thinking.

Letters to the Editor

MECHANISM AND PURPOSE

SIR,—In your leading article of Jan. 7 you point out ith clarity—I believe for the first time—that avoidance the unnecessary use of hospital beds and the ising of the level and prestige of general practice e complementary aspects of the same problem.

A certain proportion of patients are in hospital because *is only there that their disorders can properly be dealt* ith; this applies to most, though by no means all, rgical patients. But an increasing number of patients e there not for treatment but for investigation. Many these are not acutely ill and do not stand in need of killed nursing care; none the less they occupy expensive eds.

A major part of this investigation demands the ervices of the pathological department of the hospital; ut given a pathological department staffed, equipped, nd constructed so as to make possible the reception of uch patients, much of this work could be done either without the patient's admission to hospital at all or with admission only for the final steps of the investigation nd for treatment.

To this end the establishment of certain general principles is necessary; and the first of these is that the pathological departments of all general regional hospitals hould be freely and directly open to use by general practitioners. This principle has long been accepted by the Association of Clinical Pathologists and has been rigorously put forward by representative pathologists within the British Medical Association; whether it can be *officially described as B.M.A. policy, I am not certain.* It is already the established custom in a very large number of regional hospitals and should become universal.

It should be the right of the general practitioner to send specimens *from his patients for examination to the* pathological department of his regional hospital at any time during working hours and to receive the report as soon as available; it should also be his right to send the patient in the flesh to the pathological department for the opinion of the pathologist and the collection of such specimens as the pathologist may deem appropriate. To allow *patients complete freedom of entry to the* department would obviously entail an intolerable dislocation of the department's work; certain hours each week must therefore be set apart for outpatient clinics at which the patient, bearing a letter from the doctor, can present himself for examination and for the collection of the appropriate specimens, *the* results being reported to the practitioner. Such outpatient sessions have for years been the established custom in the pathoogical departments of many of what are now the regional hospitals; regional boards might well see to it that the custom becomes universal.

The provision of such facilities will do much to bring he general practitioner back into that place in the economy *of medicine* which he cannot occupy so long as he is debarred from direct access to the opinion of the pathologist. But something more is required. To ensure that the general practitioner regains that place from which he is rapidly slipping, as the person responsible for the care of the patient, *it is essential that until and unless* the patient actually passes from his care these rights shall appertain to him and to him alone.

It is therefore essential that the principle be clearly established that until the patient comes into hospital or into the care of a clinic or hospital department, only the general practitioner in charge of the case shall have the right to refer either the patient or specimens from the patient to the regional-hospital pathological laboratory for examination under the terms of the N.H.S., and *that the report of the pathologist shall be made to that* practitioner. I believe that there are few single measures which would be more effective than this in maintaining the general practitioner in his rightful position in relation to the patient.

My remarks are to be taken as referring only to regional hospitals; the primary function of these is the care of the sick and their return to active life as soon as may be; to them research, although altogether desirable, must be in the nature of an epiphenomenon. The *hospitals under the control of boards of governors are in* different case in that they have onerous educational and other duties, and by their nature research is an essential. Concerning them I do not pretend to speak.

But even for the pathological departments of regional hospitals *something more is necessary than the establish*ment of general principles. To undertake this work for the general practitioner they must be suitably constructed or reconstructed, staffed, and equipped. Few of them have waiting or examination room accommodation; if they are to perform this work with competence these must be provided. Many of these regional departments are already doing this work, albeit under difficulties; and as matters now stand, so great has been the expansion of the hospital service in pathology since its reorganisation by Sir Philip Panton during the late war, that it is to be doubted whether there are in England and Wales any major regional hospital departments of pathology incapable of undertaking it.

The Royal Hospital, Wolverhampton. S. C. DYKE.

SIR,—I cannot say how pleased I was to read your leading article of Jan. 7 and how much I agree about the dangers inherent in regional hospital boards controlling practically all the specialist talent.

Whatever the situation may hold for other branches of medicine, and quite apart from questions of economy, in psychiatry in particular any undue emphasis on the hospital side runs counter to all modern psychological methods. Before the introduction of the N.H.S. there were major advances towards early and preventive work with *patients in their own homes; in fact the whole* trend was to get away as far as possible from the mental hospital with its unfortunate associations. This development could not of course apply to the more severe psychotics needing segregation by the very nature of their illness, for whom the specially designed mental hospital was the only retreat. But the "new" psychiatry took a tremendous step *forward when it broke the* bounds of the mental hospital and opened up large fields previously closed and even now only partly explored. One has only to think of progress in the treatment of the neuroses during the last generation and the recent advances in psychosomatic medicine to see where we were heading.

Unfortunately the bias mentioned in your *article bids fair to halt or even to reverse this emancipation of* psychiatry. The psychiatrist is being yoked again to the mental hospital or the mental wards of the old municipal hospital, and the new fields are being starved of talent. No-one would oppose raising the standard of the mental-hospital staff and improving treatment facilities there, but the policy of attempting to make the mental hospital "the focus of treatment" in psychological medicine (to use an expression put to me by one medical superintendent) is, in my opinion, a decidedly retrograde step and certain to end in failure. The wider fields of psychiatry are bound to suffer, for they need a very different emphasis in training from that given to those practising the treatment of well-established mental disorders.

Mental hygiene means far more than attempts to cure certain mental diseases, just as preventive medicine is not just the treatment of physical diseases. In psychiatry, perhaps even more than in other departments of medicine, early and preventive treatment and all that is implied by the notion of mental health, is bound up with the home. Modern teaching is quite clear on the point that as far as possible it is the individual in his or her own home setting that is the most hopeful object of our attentions; I cannot see this objective being seriously approached by the psychiatrist based on the mental hospital.

Leeds. H. EDELSTON.

THE HEALTH OF NURSES IN HOSPITAL

SIR,—In Dr. Court's article of Nov. 12, in the letters that have followed it, and in the editorial comment on Dec. 31, it has been taken for granted that the higher incidence of tuberculosis among nurses as compared with "other professional women of the same age" is due to the greater exposure to infection of the former. This involves the assumption that the two groups are more or less similar in other respects.

During the period covered by Dr. Court's survey, the approximate average working week in six voluntary training hospitals (three Irish, three English) consisted of 64½ hours, varying from 60 to 72. The number of hours worked averaged 11 (10–13) on a full working day, which occurred six days per week in four hospitals and three or four days per week in the other two. The length of the working day in all six hospitals was either 13 or 14 hours. Night duty varied from 10½ to 12 hours, and the length of time on duty, without a night off, was twelve days in three hospitals, four weeks in two, and eight weeks in the other. In all the hospitals nurses off duty remained in, and those on night duty rose early in order to attend lectures, and of course they had to study and prepare for examinations during their free time.

I can think of no other group, of whatever age or sex, whose working hours are as long as these; and considering the strenuous nature of their work, it seems that nurses are among the most grossly overworked members of the community. This is quite sufficient to account for the high incidence of tuberculosis among them, and it is wrong of hospital authorities to force girls in late adolescence and early adult life to work under such conditions. It is doubly wrong, of course, when they are also exposed to infection, particularly in the case of girls who are tuberculin-negative.

The other two groups in which the Prophit survey shows the incidence of tuberculosis to be higher than in controls are in much the same position as nurses. The members of the family of an open case are usually exposed to the same forces, hereditary, economic, and emotional, that contributed to the development of the disease in their relative. Medical students spend a normal working day at lectures and classes, after which the greater part of their work has still to be done. Because they are dependant on their parents at an age when wage-earners have acquired dependants of their own they are likely to be either maladjusted or irresponsible. Other students work under much the same conditions, but their courses are shorter, less arduous, and very much more practical than that in medicine.

In any of the three groups, it is only possible to attribute the high incidence of tuberculosis to increased exposure, if one assumes that infection with tubercle bacilli is the only essential factor in the ætiology of tuberculous disease. This assumption is so unjustifiable that no-one would admit to being guilty of it. Nevertheless, workers in tuberculosis services make it the basis for most of the preventive measures—as must be clear to those who have followed the correspondence in your columns on the control of tuberculosis.

Since long before the tubercle bacillus was discovered it has been well established that tuberculosis is preceded by a "predisposition" or lowering of resistance, the causes of which are not all known. But among the causes are overwork, lack of sleep, poverty, and an all of which can be avoided more easily than can tubercle bacillus. To lose sight of this fact now can lead to an increase of the already far too preva tuberculosis-phobia.

Dublin. SEAMUS O'DAL

DEOXYCORTONE ACETATE AND ASCORBIC A IN RHEUMATOID ARTHRITIS

SIR,—I have applied the method described by Le and Wassén[1] in 9 cases of chronic rheumatoid arthr and have obtained results identical with those descr by these workers.

On the supposition that the therapeutic effect of t method is due to the alteration of deoxycortone int "cortisone-like" substance through the redox act of the ascorbic acid, I have used for the same pu other sterones. The intramuscular injection of b testosterone (25 mg.) and progesterone (2 mg.) follow by 1 g. of ascorbic acid, injected intravenously, ha produced the same therapeutic effect as the method Lewin and Wassén. Total aqueous extract of adre cortex ('Cortine') and of œstrone were less active; dehydrocholic acid proved completely ineffective.

It seems that ascorbic acid may profoundly alter pharmacological action not only of deoxycortone but of other hormones connected with the function of adrenal cortex. This change is not associated decrease in the number of blood-eosinophils—a decr demonstrated by Spies and Stone (Jan. 7) a administration of adrenocorticotropic hormone. three cases of eosinophilia I found no change in eosinophil level during the six hours after injectio 5 mg. of deoxycortone, or 25 mg. of testosterone, 2 mg. of progesterone, each followed by intraven injection of 1 g. of ascorbic acid.

Radogoszcz Municipal Hospital,
Lodz, Poland.
MARCELI LANDSBER

SIR,—The preliminary communication of Lewin Wassén[1] on the treatment of rheumatoid arthritis w deoxycortone acetate and ascorbic acid prompted me try this treatment on outpatients. The further cor spondence, which has varied in opinion from Le V and Loxton's[2] enthusiastic reports to Kellgren' very depressing remarks, has stimulated me to wr and mention the results I have had in the treatment seven cases.

I do not propose, at this stage, to go into any deta and want merely to state that all seven, which we quite unselected and taken as they appeared in m outpatient clinic, have shown improvement to a great or lesser extent. I have been seeing them all regular for periods varying from three months to a year, a no form of therapy has been of any avail until now.

One of the seven, a very acute case which has b getting steadily worse for the past six months, show quite a dramatic improvement. Of the other six, whi were all chronic, one case produced the startling result which Lewin and Wassén report. She had immediate symptomatic relief, and now, after five injections giv in the course of three weeks, is completely symptom free and is walking better than she has done for eight year All her joints are symptomatically and clinically normal where before she had considerable swelling and pai Her last injection gave symptomatic relief for seve days.

The others have been slower in their response an have shown improvement only after 3–5 injections give at short intervals. Of these, a lady of 63 is better tha she has been for over a year. The improvement

---

1. Lewin, E., Wassén, E. *Lancet*, 1949, ii, 993.
2. Loxton, G. E., Le Vay, D. *Ibid*, p. 1204.
3. Kellgren, J. H. *Ibid*, p. 1108.

e other four has been less dramatic but always quite finite, both symptomatically and clinically.

I think that this form of therapy should be extensively ed on as many patients as possible, and the results refully assessed. The fact that no improvement may obtained after one, two, three, or even four injections ould not discourage one from continuing, since provement may be slow in starting.

It is too early to be unduly cheerful or to make travagant claims, for there has hardly been time yet r side-effects to show themselves; but I would suggest at those who have found no effect from this treatment n their cases should both persevere and check their chnique.

St. Bartholomew's Hospital,
London, E.C.1.

JAMES A. ROBERTSON
Casualty Physician.

SIR,—I have used the method reported by Lewin nd Wassén in four cases of established rheumatoid rthritis. The results, contrary to Dr. Kellgren's xperience, were far from unsatisfactory.

The patients were women, aged 36, 42, 28, and 60, ho had suffered from the disease for 8, 2, 1, and 1 years espectively. They were more or less crippled and com-laining of pain which was at times very severe and or which they had tried without avail all sorts of nalgesics—including morphine in one case.

They all responded within 10–30 minutes to the com-ined administration of 5 mg. of deoxycortone acetate 'Doca') and 1 g. of ascorbic acid injected intramuscu-arly. Pain was nullified in all cases, and mobility at east partly restored. In fact, one patient, bedridden for he last eighteen months, could walk unaided for the first ime after the second injection. The relief lasted 6–8 ours after the first injection and 16–24 hours after the ighth injection (the last so far given). All the patients re very enthusiastic and thankful, being able to perform nost of their household work without pain.

Being cheap and apparently without disadvantages the method is, I suggest, worth a full trial.

Bagdad, Iraq.

FAYSAL NASHAT.

SIR,—This correspondence, from many reliable sources, reveals wide divergence of results and opinion. In my letter of Dec. 17 I suggested a reason for this, and the report from Leeds[1] supported my supposition, in that of the 17 cases, 15 were inpatients among whom there was only one doubtful gain, whereas both the outpatients gave a reasonably positive response. I further indicated that if hormonal deficiency was merely a dominant factor in rheumatoid arthritis the method could not be expected to do more than alleviate the symptoms caused by some form of adrenal deficiency.

Elsewhere I have put forward a proposition that all rheumatic diseases have a common factor, which is probably infective, and that the variations are due to contributory factors which may dominate the picture.[2] Prof. J. W. McNee's[3] account of the most recent American work on 'Cortisone' and the adrenocorticotropic hormone indicates that the improvement obtained in rheumatoid arthritis is not specific for this condition and that these substances are bringing about improvement in other pathological states presumably arising from adrenal deficiency.

In these circumstances, a review of the cases of "rheumatoid arthritis" which have not responded seems to be desirable. A typical rheumatoid arthritis about which no clinician would argue is one where there is a prodromal stage signified by fatigue, chilliness, vague migrating aching and stiffness, mild sweats, vasomotor disturbances, and tachycardia; anorexia and loss of weight soon follow and the diagnosis is made when swelling and pain develop in the joints. The prodromal stage may last only a few days or as long as several months. The blood-sedimentation rate is nearly always much increased and there is some microcytic anæmia. Unfortunately, rheumatoid arthritis reaches the physician when the condition is established and the dominant feature is arthritic involvement, so that these earlier symptoms which might suggest adrenal-cortex dysfunction are overlooked. On the other hand, there are many cases described as rheumatoid arthritis where this prodromal picture is never evident and the first signs are those of a primary attack on one or more joints. These patients do not lose weight; sometimes they even gain weight, particularly where the disorder develops about the menopause. These cases, then, are not likely to benefit from this new form of therapy, and indeed may be made worse by gland overstimulation or replacement of hormone which is already there in sufficient quantities.

I have now treated about thirty cases, some in advanced stages of rheumatoid arthritis and some in the very early stages, and I have sufficient data to confirm the statements made in this letter.

To summarise, I would say that the only cases likely to benefit from this form of treatment are those of rheumatoid arthritis associated with loss of weight, depression, vasomotor disturbances, and loss of locomotive power, which is limited not by pain alone but by an intrinsic muscle wasting—and only when they are in a period of relapse. In treatment account must be taken of the physiological state of the body and of the capacity of the body-tissues to effect stability. To underline this, I would refer to the good effects of controlled doses of thyroid in thyroid deficiency (cretinism) and the ill effects of overdosage; there is a stage when equilibrium is attained and must be respected.

London, W.1.

SYMPTOMATIC TREATMENT OF HYSTERIA WITH INTENSIFIED ELECTROCONVULSANT THERAPY

SIR,—The intensified method of electroconvulsant therapy (E.C.T.) described in 1948[1] is being used at this hospital for the symptomatic treatment of hysteria.

It was confirmed that hysterics responded badly to normal methods of E.C.T., but the improved response of depressives to intensified E.C.T. suggested that hysterics might also respond to this method. Intensive E.C.T. has the advantage that the risk of fractures is virtually eliminated; among the 576 cases treated in 1948 no fractures occurred.

Premedication consists of 'Sodium amytal' gr. 3 half an hour before treatment. An initial stimulus of approximately $1^1/_2$ sec. at 150 volts is given; and after a pause of about 3 sec. extra stimuli of 1 sec. duration are administered with approximately $^1/_2$ sec. intervals between each. At the first treatment seven extra stimuli are given. On each of the next three days the number of extra stimuli is increased by one, up to a total of ten; and at this level—an initial stimulus plus ten extra stimuli—treatment is continued daily until the presenting symptoms improve. Exact timing is not essential, but each stimulus must last at least 1 sec. A suitable apparatus had to be developed since it was found that existing types could not give sufficiently long stimuli, or repeat them rapidly enough.

At first the cases of hysteria were treated as outpatients by the technique that had proved successful with depressives.

The patient attends hospital on alternate days at 10.30 A.M. The less severely ill come to hospital on their own; but after treatment all are taken home by car, and there must be relatives at home to look after them. They receive sodium amytal gr. 3 and after removing their outer garments get into bed. Treatment is given at about 11 A.M., and they return home at about 3 P.M. Since the average case requires less than four treatments, the whole course is usually completed in one week.

---

[1] Page, L. G. M., Russell, R. J. *Lancet*, 1948, i, 597.

Whilst the depressives responded well, with a recovery-rate of over 90%, the hysterics responded less well and some 38% of these had to be admitted for further treatment. The failure of outpatient treatment was thought to be due sometimes to the effect of mal-suggestion by over-sympathetic relatives between treatments. To overcome this difficulty, hysterics are now treated as inpatients.

It was soon realised that the essentials for successful treatment of hysterics were (*a*) rapid removal of symptoms, followed by (*b*) rapid rehabilitation and return to work. The following technique is now used.

The patient is admitted on a Monday morning and given intensified E.C.T. on the Monday (1 + 7 stimuli), Tuesday (1 + 8), Wednesday (1 + 9), and if necessary on Thursday (1 + 10). Treatment is stopped as soon as symptoms are relieved.

The treatment produces some amnesia; the patient forgets the symptoms, and no further mention is made of them during his stay in hospital. About 2% of the patients develop acute psychotic symptoms whilst undergoing treatment. They may become hallucinated, deluded, or aggressive, and indicate the presence of a previously unsuspected underlying psychosis. The condition clears in a few days with rest and sedatives. On the Thursday and Friday the patient is encouraged to undertake exercise, routine cleaning duties, or work in the hospital grounds. During this stage the assistance of well-trained nurses is invaluable, since they can persuade patients that they are now able to do normal things and that any minor aches and pains will soon pass off.

The patient is discharged on the Saturday with strict instructions to return to normal work at the beginning of the next week. If patients are kept longer in hospital they react unfavourably to contact with other patients, tending to assimilate new-found symptoms; and the prognosis then becomes poor.

Experience with intensified E.C.T. in depressives and hysterics is summarised in the following figures:

	No. of cases	*Average no. of treatments*	*Satisfactory response (%)*
Outpatients			
Depressives:			
Female	63	.. 2·9 ..	91·3
Male	39	.. 3·1 ..	91·1
Hysterics:			
Female	17	.. 3·3 ..	64·7
Male	8	.. 4·0 ..	62·5
Inpatients			
Depressives:			
Female	114	.. 3·9 ..	90·3
Male	76	.. 3·7 ..	92·8
Hysterics:			
Female	22	.. 3·0 ..	90 +
Male	13	.. 3·4 ..	90 +

Cases treated as inpatients have included examples of conversion, fixation, and anxiety hysteria, The following three cases are typical of the group.

CASE A.—A farm labourer, aged 48, with a good work record and no previous history of psychoneurosis. In November, 1948, he had a bilateral herniotomy which took a normal course, but during convalescence he developed a drawing sensation and pain in the scrotum and down the inside of each leg. The pain was worse when he sat down, and was only relieved by lying in a warm bath. He had been unable to work for seven months, but responded to intensive E.C.T. and returned to work in one week.

CASE B.—A police constable, aged 28, of good intelligence and personality. He had been troubled with headaches for six months and no organic cause could be found. The precipitating factor was a syphilophobia, which had not responded to repeated reassurance. He responded to two days of intensive E.C.T. and returned to duty in five days.

CASE C.—A general labourer, aged 52. Of low intelligence and hysterical personality, he had been unemployed for over two years. He suffered with vague abdominal pains, which had been incorrectly attributed to diverticulitis. Ultimately he was sent to a training centre for disabled persons to learn light leather-work. After one month he was admitted to a general hospital for further abdominal investigations, which proved negative. Whilst in hospital his condition deteriorated rapidly and he was unable to walk or lift his arms to feed himself. The whole condition cleared with three days intensive E.C.T. and he returned to the training centre in week.

All the hysterics treated by this technique ha responded satisfactorily and have been discharged fro hospital. As only 65 cases have been treated so fa it is impossible to give an accurate recovery-rate, but would appear that a rate higher than the 90% four in depressives can be expected.

A precise follow-up of all the cases has not been possibl but the relapse-rate has been less than 10% over a peri of six months following treatment. The cases that hav relapsed have been those of severe hysteria in patien with inadequate personalities who have shown numerou hysterical phenomena for many years.

My thanks are due to my colleagues and the nursing sta for their assistance; and to the Reeves Electrical Co Baldock, Herts, for their coöperation in producing a suitab E.C.T. apparatus.

Three Counties Hospital,
Arlesey, Beds.

R. J. RUSSELL.

THE FIRST MEDICAL EXAMINATION

SIR,—May I take up some points made about m article[1] by Mr. Hentschel in his letter of Dec. 17?

I did not say that I thought the purpose of the fi M.B. examination was to select appropriate students fo medical career. I was concerned not with purpo but with observable effect; I pointed out that t examination *does* select, and with this Mr. Hentsch seems to agree.

Mr. Hentschel attributes the high failure-rate in t external first M.B. examination to the inadequate traini of the candidates, especially in schools; and in suppo of this he draws attention to the much higher pass-ra (60%) in the internal examination (the pass-rate i external first M.B. in July, 1948, was 13% and for high school certificate [H.S.C.], giving exemption from fi M.B., 30%). Might it not be that what constitutes "adequate standard" is differently interpreted different examiners? I do not think that the teachi in many London schools compares so very unfavourab with that in the colleges and medical schools as M Hentschel thinks. It is surely the experience of mo university teachers that many boys and girls receive a excellent background of science at school. Many schoo still have experienced teachers and good facilities fo practical work; as far as time is concerned, only on session is assigned to internal first M.B., but two or thre years to H.S.C. It would be interesting to know how the failure-rate in the London examinations compare with that in other areas.

The discrepancy between the pass-rates in the interna and external examinations is disquieting, not only because it may do injustice to individual candidate but for a further reason. At University College we find that the applicants for admission to the intermediate class, which gives exemption from first M.B., tend to have weaker school records than those who apply for admission to the second M.B. class, having got, or hoping to get, first M.B. exemption externally. This is presumably because of the system by which scholarships are awarded; the brighter pupils try to get exemption from first M.B. at the same time as they attempt to get scholarships on H.S.C. and other examinations which necessitate two or three years' work in the sixth form. If this is the case in other medical schools, the lower pass-rate in the external examinations tends to deprive the medical schools of some of the brighter pupils, while the higher internal pass-rate ensures safety for a larger proportion of potentially weaker students.

The problem is, to decide wisely what is for medical students an adequate knowledge of the basic sciences.

CONTROL OF TUBERCULOSIS

ɪʀ,—It is with some hesitation that I join in this cinating controversy, for I am in the embarrassing ition of being able to see both sides, having been a st-clinic physician immediately before I became ysician-superintendent of a sanatorium. However, re appear to me to be important issues involved. r example, the increasing use of active treatment, and ecially streptomycin, outside chest hospitals and atoria to my mind makes increased liaison between rkers in such institutions and chest-clinic physicians urgent necessity.

For the sake of brevity, I will make the following gmatic statements. (1) Like peace, the treatment of uberculous patient is indivisible, beginning on diagnosis d ending only when his name leaves the register. It consists of many different facets, domiciliary, nilial, psychological, institutional, rehabilitating, &c.) Though the form of approach changes, the object of r attentions—the patient—remains the same person ether he is at home or in a sanatorium.

All this would seem to indicate that one physician ould supervise all treatment throughout the patient's reer, perhaps the tuberculosis officer or perhaps the natorium physician. In the past this has been possible ere the institution is small, and it is now attempted by me tuberculosis officers who have general hospital ds at their service and make use of them as pseudo-natoria. But I believe that the work of a good chest inic is quite enough for one man and that its interests e different from, if as valuable as, those of the sana-rium physician, and that the work of the up-to-date natorium is as intricate and all-absorbing. Also I ink it is true that nothing can replace a stay at such sanatorium during the patient's career, not only for e intensive and skilful treatment that can be carried it, but also for its educative value.

But the two spheres cannot be wilfully divorced. any sanatorium physicians believe that the only course hich is ethically correct is to keep and treat each atient till he is almost healed or definitely unhealable. et many patients can finish off their treatment safely t home after a reduced period in the sanatorium, and us be replaced more quickly by others. (It is important at we who work in sanatoria should understand the agedy of the long waiting-list in terms of living dividuals.)

Again, whilst a patient waits to enter the institution, here is often a natural and overpowering urge in the berculosis officer to institute active treatment, and at resent this is done without any relation to the course hich therapy may take in the special hospital. Once here, success will often depend on underlying psycho-gical factors, which are almost certain to be influenced y what is going on in the patient's home.

Tuberculosis must be tackled by a team and this team ust consist of sanatorium physician, thoracic surgeon, elfare workers, and—not least—the chest-clinic hysician. I believe that the last of these should be as elcome in the sanatorium, and his advice as important here, as conversely should be the sanatorium physician n the dispensary (where either will get the time for this s a different question!). (Unlike Dr. A. P. Ford, I hold hat the doctor immediately overseeing the patient nust, however, have the last word in his management.) ncidentally, there would be much to be gained by research being undertaken by the team as a whole, for there are vast, almost unmapped fields in the dispensary files.

One or two practical suggestions. Each sanatorium gets its patients from a definite area; the chest clinics in that area should provide the outpatient physicians to the sanatorium team. It would be worth while, I believe, for assistant-physician posts at chest clinics not to be permanently filled but occupied in rotation by less senior medical officers from parent sanatoria. And, finally, there should be regular consultations (staff meetings or on rounds) between the two forms of specialist, to discuss specific cases.

The correspondence has discussed many problems in the difficult field of tuberculosis control. My letter must be regarded as an addendum to that of Mashiter and others (Dec. 10), and as a plea for coöperation on a broad front.

King George V Sanatorium, Godalming.
J. V. HURFORD.

PLACEMENT MEDICAL EXAMINATIONS

SIR,—Dr. Todd's observations (Dec. 31) on the principle of medical examination for civilian jobs are refreshing, and will have served a useful purpose if they make medical officers who habitually carry out this type of work pause to examine their basic concepts. These observations may, however, give to others a mistaken impression of the way in which pre-employment examination operates in industries where it is normal practice.

In industry, in my experience, the doctor is never the sole arbiter of a man's fitness for a particular job. For example, during 1949 I examined 2337 applicants for employment in a large factory. Of these, 14 were rejected on account of some disability which the examination disclosed; 21 others were not engaged after the medical examination, for other (non-medical) reasons. During the same period, 2181 applicants were rejected by the factory employment bureau as unsuitable, and were therefore not submitted for medical examination. In other words, out of a total of 4518 applicants about 48% were pronounced unsuitable by non-medical personnel, and 0·3% by the doctor. Thus even if it were conceded that for a doctor to forbid a man to undertake a job on account of disability is an infringement of the liberty of the subject, the extent to which it has happened here is negligible.

But let us consider further this question of the liberty of the subject. The industrial medical officer who examines a candidate for a job in a factory has, or should have, an exact knowledge of what that job entails, in regard both to toxic and other hazards and demands on physical capacity. The candidate, on to whom Dr. Todd would put the onus of deciding his own fitness for the job, does not possess this knowledge: moreover, he is usually being driven by economic necessity to seek the job, so that to depict him as a free agent who may voluntarily decide to endanger his own health by undertaking it against medical advice is sheer nonsense. Admittedly a man's eagerness for employment is a factor which should weigh with the medical officer in deciding whether to accept him, and I agree with Dr. Todd on the necessity for flexibility in medical standards—the personality of the individual and the nature of the work must both be considered in every case; but ultimately the decision must be the doctor's, and should not be shirked by him.

Our laws—in my view, rightly—interfere with the right of a man to choose to take his own life, or to destroy himself more slowly with morphine, cocaine, or heroin. Similarly, by our factory legislation we have taken away the "rights" of children to work underground in the mines, or to work in cotton-mills for eighteen hours a day. We have rejected the view that the employer need do nothing to improve unhealthy working conditions because the worker is free to refuse the job. The worst social abuses of the Industrial Revolution were justified by this fiction. In fact, of course, the worker's freedom was an illusion. The awakening of public opinion and the rise of the trade-union movement forced legislation to remove these and similar fictitious "rights of the individual," substituting for them some very solid benefits.

Thus, although Dr. Todd wisely qualifies the supposed right of the individual to accept a job which will endanger his health, the general acceptance of the principle he advocates would put back the clock a hundred years. I cannot believe this to be his intention.

Port Sunlight, Cheshire. F. H. TYRER.

SIR,—We have read with considerable misgiving Dr. Todd's article, in which he states: "We may therefore conclude that there is no real place for a medical examination as a part of the selection of adults for jobs." He writes of injustice towards employees and infringements of their liberties as results of pre-employment examination. We consider that these remarks are incorrect and misleading.

No experienced industrial medical officer doubts the desirability and value of pre-employment medical examination. The duties of, and ethical rules for, industrial medical officers drawn up and published by the British Medical Association support this contention. The incidence of illness, the loss of working hours, and the risks to other employees—to say nothing of loss of efficiency due to faulty job allocation, which is more liable to occur where there is no pre-employment medical examination—are alone sufficient to justify such a procedure.

Would Dr. Todd suggest, as he certainly implies, that there should be no inquiry and investigation into such conditions as pyorrhœa, septic tonsils, chronic aural discharge, previous intestinal disturbance, or pyogenic conditions of the hands of persons whom it is proposed to employ in the preparation and handling of food?

It has been estimated within recent years that for every day lost to industry by industrial disputes 270 days are lost by illness; and surely nothing that would reduce this figure should be neglected. No industrial medical officer is able, or wishes, to *forbid* any prospective employee taking a job. His function is purely advisory to executive management and is analogous to the function of a medical officer in the Services towards the commanding officer.

It is our experience that employees or prospective employees are grateful for kindly and sympathetic advice concerning the work for which they are best suited and the types of occupation which they should avoid. For example, a man with monocular vision working as a crane-driver would constitute a considerable potential danger to his workmates, whereas he would be in no way handicapped working as a fitter. The worker himself may be safeguarded as a result of the examination—for example, if he has hyperpiesia and is prevented from lifting heavy weights continuously and over long periods.

Dr. Todd's statements are absolutely contradicted by the experience of large numbers of industrial medical officers over many years. To dispense with pre-employment examination in industry and with the industrial medical officer in his rôle as a member of the team performing job allocation would be retrograde.

societies. I don't possess a microscope. I don't kno
But here, at any rate, is an exact picture of what h
regularly happened to at least one person—and possib
to many thousands more—for several years. Perhaps
may provoke a fruitful idea in the mind of somebo
poring over the problem of the "common cold," the
various types of "influenza," and the amorphous mas
of complaints, sometimes labelled one, sometimes the
other, and sometimes "chill," "catarrh," "feveris
chill," or "pyrexial catarrh," according to the certifying
doctor's whim, his erudition, or the time at his
disposal.

But by now, I hope, the deeper significance of this
letter has begun to dawn. For it was out of a similar
chaos, known as continuous fever—and with no aid from
bacteriology—that typhoid and typhus were ultimately
disentangled. By whom? *By patient and exact clinical
diarists.* And may it not be true that this chaos also—
so huge in its aggregate of discomfort and sick absence—
really consists of several disorders just, in their way, as
distinct? And that being so, is any real progress likely
to be made until they have received, in respect of exact
histories, very much more clinical attention than has
yet been bestowed upon them? It may be argued that
the majority of sufferers seldom come under medical

e and that; when they do, it is only too easy for a doctor lightly to dismiss them with one or other e above scraps of terminology. But there are, in islands, in the shape of these very doctors, at least 0 trained observers, who must themselves be sional victims. Surely these are enough for an uate beginning. But why call this particular entity enza Cosmo ? Well, I have my private reasons ; and, e present state of our knowledge, why not ?

STERILISATION OF POLYTHENE TUBING

r,—Dr. Galley's letter of Jan. 7, in connexion with note published on Dec. 24, is fair comment on the ility of fine 'Polythene' catheters after sterilisation boiling. I am aware of the mishap he reports, and hin the last three months have seen four cases where tubing has broken at the skin margin—one in the ral canal and the other three in the lumbar region. three of our cases, the break occurred after the tubing l been in position for 12 hours, and in the other er 48 hours. In many dozens of cases, however, we ve had no trouble with this technique in prolonged gical operations of 2–4 hours' duration. There is real risk of breakage in prolonged cases, and until bing of more resilient material is available, its use ould be restricted to gravely ill patients in whom ntinuous extradural block offers the only reasonable pe of survival—e.g., the eclamptic woman in whom the od-pressure cannot be controlled by more conservative asures.

Should the catheter break, the results are of no great nsequence. In three of our cases a small incision der a local anæsthetic was made within 12 hours of cture and the piece easily found and withdrawn. the fourth case, no attempt was made to recover the theter for three weeks. It could not be found, and it s reassuring to note that experimental findings were nfirmed in that there was no evidence of tissue reaction.

PEMPHIGUS VULGARIS TREATED WITH AUREOMYCIN

Sir,—Dr. Bettley's account last week of a successful ial of 'Aureomycin' in a case of pemphigus vulgaris, ompts me to record my own experience of this eatment in a case under my care.

He was a well-preserved man, aged 89, who was admitted Addenbrooke's Hospital, Cambridge, on Dec. 6, 1949, ith the typical clinical picture of severe pemphigus vulgaris two weeks' standing. He had numerous blisters on the ms and legs, and circinate patches of dusky erythema on e trunk. The eruption began on the feet.

The progress of the eruption was rapid, and uninfluenced sulphapyridine ; the bullæ increased daily in number and size, reaching 4 cm. in diameter. He remained apyrexial d in fair general condition until Dec. 20 when erosions peared on the palate ; his general condition was obviously teriorating, his appetite began to fail, and almost the hole skin surface was involved—blistering, ulcerated, or ythematous.

I started aureomycin on this day with 250 mg. 6-hourly y mouth, and increased it to 500 mg. 6-hourly next day, ntinuing it at this level without toxic effects. After 48 hours e patient's general condition improved, and the few fresh listers were small. On the third day no fresh blisters ppeared, for the first time since his admission. He felt etter and could move in bed without much pain ; the lcerations were drying and the erythematous plaques fading.

This striking improvement lasted six days, during which the ealing areas of skin began to pigment. But on Dec. 25 esh small blisters appeared on his abdomen and legs. They radually increased in size and extent, his general condition eteriorated, and he died on Jan. 7. The aureomycin had een discontinued a week previously, since it was no longer roducing any response.

Pemphigus vulgaris is characterised by remissions and relapses, but the improvement in the patient's condition and the cessation of blistering during the administration of aureomycin parallel Dr. Bettley's observations. A similar case has been reported by Philip,[1] whose patient also died after an initial improvement in the skin on the third day.

Many dermatologists have already started using aureomycin for pemphigus vulgaris, and assessment of results at this stage is likely to be premature, especially since the condition is notoriously capricious in its response to a variety of agents. But the hope engendered by these three cases warrants at least further trial of the drug early in the course of a disease which usually proves fatal.

Addenbrooke's Hospital, Cambridge. C. H. **Whittle.**

TUBERCULOUS ABSCESS AT SITE OF PENICILLIN INJECTIONS

Sir,—I would like to reinforce the plea by Dr. Douglas, on Jan. 14, for better syringe sterilisation and user technique. I feel sure that contamination of the injection material by dust-laden air or failure in aseptic technique is the cause of the accidents, as I have stated before.[2] I know from experience that (1) exclusion of ward dust from solutions, and (2) conscientious and good aseptic technique will prevent these unpleasant consequences of exogenous infection. Training in bacteriology for all nurses is also indicated.

St. Margaret's Hospital, Epping, Essex. **Frank Marsh.**

EPILEPSY AND ORGANIC DISEASE

Sir,—I am grateful to Dr. Dalton (Jan. 14, p. 94) for his reference to my address on epilepsy to the Manchester Medical Society (*Lancet*, 1949, ii, 994) ; and he is right in saying that I drew attention to organic disease as a cause of epilepsy, especially in later life. His partial quotation of my figures is, however, somewhat misleading. It is true that of 25 deaths in patients who had their first fit after the age of forty, the cause of death in 10 was a cerebral tumour. But the 25 deaths occurred in 100 patients with the same age of onset of epilepsy, and the remaining 75 showed, when re-examined not less than three years later, no sign of cerebral tumour. In this series, therefore, of people over forty developing epilepsy, only 10% were subsequently proved to have a tumour. This does not diminish the importance of bearing this possibility in mind and of re-examining periodically all cases of epilepsy.

Newcastle upon Tyne. F. J. **Nattrass.**

HEAT CRAMPS

Sir,—I am most gratified that, in his letter of Nov. 19, Dr. Marsh, who has had wide practical experience in the field, expressed interest in my article of Nov. 5.

I agree with Dr. Marsh that the development and relief of cramp may involve more than simple osmotic factors. In the first draft of my article I did go so far as to suggest that the speed with which cramps were relieved by the injection of strong sodium-chloride solution was greater than might be expected with a simple osmotic mechanism; a certain natural caution, however, and the feeling that possibly a biologically minded physical chemist might make the attempt to calculate the actual time required for an osmotic transfer and show me wrong, caused me to withdraw this remark—I think in proof. But I did go so far, in my paper as printed, as to suggest that sodium chloride, by which I meant either the whole salt or one of its ions, might possibly have a specific function. The best evidence against a simple osmotic theory of heat cramp is provided by those tests in which osmotically everything was in favour of cramp developing, but in which it did not do so; it is here, I think, that the influence of the adrenal cortex may be seen, either direct or secondary to its effect on permeability as shown by recent work at Cambridge.

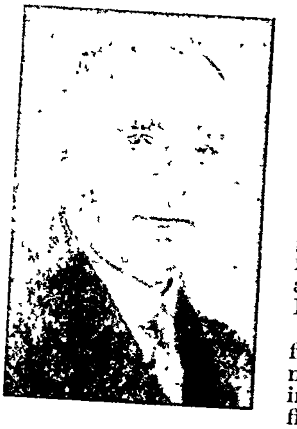
Obituary

ALEXANDER GEORGE GIBSON

M.A., D.M. OXFD, B.SC. LOND., F.R.C.P.

Dr. A. G. Gibson, consulting physician to the Radcliffe Infirmary, died at his home in Oxford on Jan. 11 at the age of 74. Inevitably, but unfortunately, the general physician who is also actively engaged in pathology is passing from our midst, and students of today are poorer for the lack of men of Gibson's type.



Born at Hull, the son of William Gibson, he was educated at University College, Aberystwyth, and at Christ Church, Oxford. In 1895 he took his B.SC. Lond. and after completing his medical studies at St. Thomas's Hospital he took his B.M. in 1901, proceeding to his D.M. four years later. From a house-appointment at St. Thomas's he returned to Oxford, where at first he held a similar post at the Radcliffe. Later he became university demonstrator in pathology, and afterwards Nuffield reader in morbid anatomy. For a time he was also in general practice in the city, but as his consultant work grew he had to give this up. He was elected F.R.C.P. in 1913 and he was appointed full physician at the Radcliffe in 1919.

Before the days of the Nuffield benefaction, the Oxford medical school was small and intimate; the Radcliffe Infirmary, with its five or six residents, was still a county hospital and not yet a great university medical centre. The army huts in the forecourt were a visible reminder of unwonted activity during the 1914–18 war. This was the setting against which Gibson spent the most productive years of his life as physician, pathologist, and Litchfield lecturer in medicine, surrounded by good colleagues who had worked with Osler and who revered his memory.

"Medical graduates who were at Oxford between the wars" (writes one of them) "remember 'the Gibber' with gratitude and affection, for he found time to share their interests and difficulties, despite his busy consulting practice and his manifold hospital and university duties. Short but well-knit and dignified, he carried himself well; he was clean-shaven, with a firm mouth, an aquiline nose, a lively voice, and a ready smile. Punctually at 20 to 9 he was in the laboratory examining the overnight cultures. 'I told you so,' he would say, emerging from the incubator and shaking off the magnifying glass so that it hung around his neck, 'it *is* a streptococcus. Now see if you can decolorise this one,' and he would give a challenging chuckle. And so another day of interest would begin for Gibson and those fortunate enough to be associated with him. A few minutes later he would be in the post-mortem room which adjoined the laboratory, deftly removing the organs and examining them in the best of north lights. 'You recall the man in the top left-hand bed in Rowney?' he would say; 'well this poor woman has what I believe to be precisely the same lesion.' He would then trace the natural history of the disease and fit it into the patient's story, enlarging perhaps, without however any note of pessimism, on our present futile attempts to treat the condition. The specimen would then be carefully placed in preservative for a future occasion. By now confirmatory tests would be ready to read in the laboratory and the first batch of reports waiting for signature, for Gibson believed that a laboratory service to be

ASSADOUR ARAM ALTOUNYAN

M.D.

HE Armenians, a gifted race, have lost their most nguished representative, and the Near East the man , introduced modern surgery and medicine. His justified the legends which his name gathered; his of work and living had the simplicity and a little he cunning which is endearing to Eastern people.

orn on March 21, 1854, he was an orphan at the age bout six, and it was said of him that he diagnosed the se of his father's death (pneumonia). At any rate n an early age he set his face against the superstitious, tom-ridden ways of thought of his place and time. pported in the bare essentials by his uncle, he had to n the scientific books he needed by doing labourer's rk and by driving donkeys—those toil-bearing creatures so much loved, though he himself was a great horse- n who with regret gave up riding after the age of iety.

American missionaries, recognising his talent, put him ough the medical school of Aintab, a provincial lege in the Turkish Empire. His postgraduate educa- n was taken in the U.S.A., in Germany under Koch, d in Vienna. He rejoined the Aintab College, working h Dr. Sheppard, and married Miss Riddall, the Irish tron there. Then began years of itinerant medicine, ng from village to village, his wife assisting him, ing first in any locality only such operations as would tainly be successful, since this modern surgery was ked on with greater horror and dread than the rbarous conventional treatment of those days. Once was accepted as a surgeon (and to do any effective rk in a primitive community, as those with such perience well know, supersitious opposition has first be overcome) he faced the really difficult surgical tasks. ith a great name in the hinterland already established, settled in Aleppo. Here, because of his Western ideas, was "the last resort"—that maker or breaker of putations. For instance the beautiful daughter of a sha, exiled from the Sultan's court, was declared by e physicians to be dying of tuberculosis; Altounyan ated her for her typhoid fever and she recovered. at was not miraculous work, but it eased the mind the pasha and that of Dr. Altounyan. The Turkish vernment henceforth would receive no health report om Aleppo that was not countersigned by him.

His first X-ray plant, the first in the Near East, was occasion of Oriental comedy. The Turkish medical icials, jealous of his fame and ignorant of the use of e apparatus, desired its possession to enhance their putation; the provincial governor accordingly ordered m to send it to Bagdad. A collection of wires, old ils, and a burnt-out tube were neatly packed and spatched, while the effective apparatus continued to used sub rosa. Some months later when the Turkish tional leader, Jamal Pasha (later to be commander- -chief) broke his leg, Altounyan X-rayed it and told mal the whole story. Jamal enjoyed the joke and the nefit, and prevented further interference with the ork.

Open and fearless in his relation to the Turkish thorities, Altounyan was trusted by them and he was le during the terrible massacres at the end of the st world war to save many of his co-religionists. His ughter smuggled Armenian children into Aleppo past e Turkish guards and fed them on Turkish army rations cured from Jamal Pasha. Kemal Ataturk, then mmanding an army, was one of his patients, and ade the matron's office his headquarters for a time. ltounyan went after the first world war to Paris to present his people at the Peace Conference.

His hospital, built in 1911, was an enterprising place. hen the therapeutic effects of radium were discovered. obtained a "bomb" of it: his was one of the first hospitals where a donor was at hand for every operation that involved shock or loss of blood; and so it went on through the decades and through the wide range of discoveries and developments of laboratory technique. His capacity to work was to the lazy Oriental incredible, as was his endurance to the Westerner; at ninety-one he performed a jejunectomy on his wife because (during the war) there was no-one else who would do the job, though his colleagues obliged by looking on. He saw patients to the day before he died. His last scientific communication,[1] made to the International Society of Surgery when it met in London in 1947, was characteristic of his careful work.

But what made him great among his people and his patients was his simplicity and care for detail; his ease in work and in his social relations sprang from his great ability combined with his humbleness in the presence of complexity. He did not start by assuming that he knew, only that he had still much to learn. Socially he never imposed on his guests; he received them just for the persons they really were.

His house in Aleppo was the gathering-place of travellers (T. E. Lawrence said of one of his carpets that "it alone was worth the sack of Aleppo"). His hospitality was Oriental without display, and Western without formality. East and West seldom meet unless there comes a man great enough to combine them. To this add the refinements of scientific thought and the directness and strength of the peasant, and it will be clear why today Armenians mourn; and we who live with different troubles must stretch our imagination before we are able to understand and acknowledge his kind of greatness.

The memorial service was in Armenian, Arabic, and English—three of the six languages with which he worked. He leaves a widow by his second marriage, a daughter, a son (Lieut.-Colonel E. H. R. Altounyan, M.C., O.B.E., F.R.C.S.), who carries on the tradition, six grandchildren (one a medical student), and four great-grandchildren. JOHN RICKMAN.

HERBERT ERNEST BATTEN

F.R.C.S.

Mr. Herbert Batten, consulting orthopædic surgeon to Charing Cross Hospital, died at his home in London on Jan. 8.

Born in 1877, the son of the late Henry Batten of Ilminster, Somerset, he was educated at Ilminster Grammar School and the University of Bristol. In 1891 he qualified as a pharmacist, but he was already anxious to become a doctor and after a few years he entered St. Mary's Hospital medical school. In 1904 he took the Conjoint qualification and after holding house-appointments at St. Mary's he decided to specialise in surgery. After several years as surgical registrar at the Wigan Royal Infirmary he returned to London to study for the F.R.C.S., which he obtained in 1914. At the West End Hospital for Nervous Diseases, where he held the post of resident medical officer under Laming Evans, his interest in orthopædic surgery was stimulated, and later he became resident surgical officer at the Royal National Orthopædic Hospital. After the 1914–18 war, during which he served in the R.A.M.C. with the rank of major as a surgeon specialist, he settled in orthopædic consulting practice. In 1919 he was appointed orthopædic surgeon to the Freemasons' Hospital (later the Royal Masonic Hospital), and the following year he joined the staff of Charing Cross Hospital. He was also on the staffs of the Royal Sea-Bathing Hospital at Margate and the St. Marylebone and Western General Dispensary.

D. T. writes: "Herbert Batten was a kind and friendly man; he was utterly incapable of any harsh action: he was always helpful, sound in advice, and justly critical. Nothing gave him more pleasure than to feel that he had helped one of his late house-surgeons or registrars in their professional climb; only those close to him would realise this, for he was by no means demonstrative but rather reserved. Indeed, he was a modest man: this accounts for his lack of writing, for he held strong views that papers should contain a real contribution; yet he practised many original methods which would have been

HE SPIRIT OF THE CHELSEA HOSPITALS

E is no particular reason why belonging to the nation rob our hospitals of the sense that they belong just h, and far more closely, to their own neighbourhood ditions. This is an old experience in national life, and ich time may teach us to apply internationally. As ferent Saxon kingdoms united to make England they lose their sense of local patriotism—on the contrary, ept it quite violently, and merely extended their beyond it to a wider concept. The hospitals can much without losing or diminishing their own local es. A sense of this truth has been responsible for the of the *Chelsea Hospitals Quarterly*, published in the ' that it would surely be a good thing if the old feeling rsonal interest in a hospital, a feeling that it was a local tion of which people were proud—and fond—could be ed under the new conditions of the National Health ."

material in this first issue goes far to foster this purpose, re is not a dull or badly written line to be found in it. iew of twenty-five years' progress in St. Stephen's al is followed by short notes on the dangers of castor printed), on a new nursery cadet scheme in the Fulham ensington hospitals, and on the physiotherapy department St. Stephen's. Miss Vera Brittain contributes a useful on What Nursing Taught Me. A section on staff es, a correspondence column, some more notes on l records, hospital history, the nurse's view and the 's view, and another quoted article on the influence ur in hospital, make up a lively little journal.

roversial, too: while praising the Fulham and Kensinglet scheme the editor urges the greater use of cadets lly aged 15–16—in the wards. Examples are not wanterious tuberculosis infection, sometimes ending fatally, lescents of this age-group allowed to work in wards, n general wards. They should not be exposed to any isk unless they are watched closely for signs of early on and unless other special precautions are taken otect them. The Fulham and Kensington Hospital ement Committee have this risk well in mind; and if elsea Group Hospital Management Committee decide pt a similar scheme they will doubtless feel equal .

RECRUITMENT OF NURSES

women are entering nursing today than ever before, demand still outruns the supply. The *Ministry of Gazette* for December, 1949, notes wastage and the on of the health services as the chief reasons for the ied need. Conditions of work are improving—fast hospitals, slowly in others. The 96-hour fortnight, ple, advocated by the Government for many years, he best part of this century by various committees g conditions, is not yet universal in our hospitals, ecause increases in staff are more readily used for new wards and departments than for alleviating the he existing nursing staff. However, the situation is steadily easier, and the Ministry of Labour and l Service has had its share in increasing recruitment. tional Advisory Council on the recruitment of nurses dwives meets regularly, the Minister presiding, and this uides the policy of the nursing services branch at the y headquarters, which in turn supervises and directs 33 nursing appointments offices in different parts of the country. These offices foster recruitment in their areas, advise new entrants and trained staff on careers, and place those looking for employment.

To interest women and men in nursing the Ministry publishes advertisements presenting the case for nursing as a profession and providing coupons which those who want more information can send to the London nursing appointments office. During the year ending Sept. 30, 1949, no less than 20,282 coupons or letters were received, about a third of them from people under 18. About a fifth were from people inquiring about employment or training; and 1689 of the applicants were actually placed in employment or training. The yield, though small in relation to the inquiries made, has meant quite a substantial addition to the country's nursing force. The mobile nursing exhibitions, described in our columns [1] in 1946, when the first vans took the road, have toured Great Britain and Northern Ireland and attracted attention and inquiries wherever they went. During the year reviewed, at least 26,400 young people and 14,000 adults saw these exhibitions—which show pictorially the stages in the life of a student nurse and the careers open to qualified nurses. The effect cannot be assessed but is believed to be good. Leaflets on general and special nursing, and on midwifery, have been widely distributed, posters have been displayed in likely places, and films have been used whenever possible. The nursing appointments offices send speakers to senior girls in schools, women's organisations, youth clubs, rotary clubs, and the like. (Incidentally, the offices give advice and information not only to nurses but to radiographers, physiotherapists, occupational therapists, and medical laboratory technicians.) They have also done much to recruit part-time nurses, who have eased the difficulties of many hospitals, especially those for the chronic sick and the mentally disabled. Between June, 1947, and June, 1949, the part-time staff employed in our hospitals rose from 12,000 to 26,000. The offices have also helped actively in schemes for bringing foreign nurses to England. In the year ending Sept. 30, 1949, the offices filled 15,400 vacancies in the hospitals—3000 with trained nurses and midwives, 6300 with students, and 6100 with unqualified staff not in training; 2100 of these were part-time and 13,300 full-time workers. The numbers of student nurses and midwives in training throughout the country have risen from 43,300 in 1943 to 57,800 in 1949, and a growing number of training schools have a full complement of nurses.

The staffing of hospitals generally must have improved, for during the year ending June 30, 1949, the numbers of nurses and midwives employed rose by about 15,000, and the number of occupied beds by 10,000. There are still 30,000 vacancies on the books of the appointments offices, however—a reminder that it is not enough to recruit nurses; we must keep them.

GRANTS FOR STUDY IN THE UNITED STATES

THE United States government announces that under the Smith Mundt Act a limited number of dollar grants are available to university teaching staff or those of equivalent academic status in other institutions and to senior research-workers who wish to visit the United States for the purpose of study, research, or lecturing. Applicants must be affiliated with an American institution of higher learning, and, if in the research group, must spend at least three months in the United States, and visiting lecturers at American universities at least six months or one semester. All applicants must be citizens of the United Kingdom. Successful candidates will also be awarded a Fulbright travel grant (see *Lancet*, 1949, ii, 1207) to cover the return fare from their home in the United Kingdom to the first point of destination in the United States. The maximum Smith Mundt grant is $2000 per annum, plus the cost of internal travel within the United States (when not covered by the Fulbright grant), plus a $10 per diem allowance during this travel. So that as many people as possible may be helped, the grants will usually be awarded to supplement inadequate dollar funds obtained from some other source. The grants will operate within the period of one year from June 1, 1950. Applications may be made by candidates who have not yet concluded the above institutional affiliation. Application forms, to be returned before Feb. 18, may be had from the United States Educational Commission in the United Kingdom, 55, Upper Brook Street, London, W.1.

University of London

On Jan. 6 the following degrees were awarded :

M.D. Branch I (medicine).—A. W. Anderson, H. J. G. Bloom, J. P. Bound, J. P. Bradshaw, F. S. W. Brimblecombe, C. J. M. Clark,* R. A. Craig, Dewi Davies, A. P. Fletcher, R. M. Hardisty, J. M. Hill, A. F. Huston, R. J. Isaac, A. D. M. Jackson, H. E. M. Kay, E. C. B. S. Keat, L. G. Kiloh, Anthony Knudsen, Michael Leivers, B. S. Lush, Ananda Nimalasuria, W. S. Peart, Eric Sanders, D. G. Sheffield, V. H. Springett,† I. McD. G. Stewart, Cecily M. Tinker, D. A. H. Trythall, J. S. Watson, P. L. Watts, J. C. P. Weber, Elizabeth Williamson.

M.D. Branch II (pathology).—G. T. Allen, W. E. D. Evans, Erich Geiringer, E. J. Harries, Emmanuel Levy, Ernst Neumark, J. A. Nissim,† Sidney Shaw, J. C. Sherris, Peter Story.

M.D. Branch III (psychological medicine).—E. J. Anthony,† R. A. Blair.

M.D. Branch IV (midwifery and diseases of women).—C. J. Champ, C. T. F. Ealand.

M.D. Branch V (hygiene).—Harry Binysh, Wickramaratchyge Ajitha Karunaratne, J. C. McDonald.

* Mark of distinction. † University medal.

Prof. J. M. Mackintosh has been appointed Heath Clark lecturer for 1951. He will deliver five lectures on Trends in Public Health in the 20th Century.

University of St. Andrews

At recent examinations the following were successful :

M.D.—Janet E. Long.

M.Ch.—J. A. Shephard.

M.B., Ch.B.—Christella A. Adamson, N. J. Allan, L. W. Betournay, R. F. Boucher, Helen H. H. Dickie, G. L. Ferguson, John Harrington, Marion C. Kerr, Helen F. McLagan, H. J. Penkala.

University of Bristol

The dissertations of G. S. Andrews and Frances B. Robinson have been approved for the degree of M.D.

Royal College of Surgeons of England

At a meeting of the council on Jan. 12, with Sir Cecil Wakeley, the president, in the chair, Sir Max Page was appointed Hunterian orator for 1951, Mr. William Doolin Thomas Vicary lecturer for 1950, and Prof. P. D. Wilson Robert Jones lecturer for 1950. Mr. R. M. Handfield-Jones was re-elected to the court of examiners and Prof. V. W. Dix and Mr. H. J. B. Atkins were elected as members of the court. Mr. D. N. Matthews was admitted as a member of the surgical section of the board of examiners in dental surgery.

It was decided that in future the annual meeting of fellows and members would be held on the day preceding the second Thursday in December and that on the same day there should be one of the statutory lectures, the monthly dinner, a "view day" in the various departments of the college, and the annual show of recent additions to the museum.

The following diplomas were granted jointly with the Royal College of Physicians :

D.I.H.—Mohamed Mohamed Abdel-Latif, D. K. Cowan, Alan David, A. W. Gardner, R. F. Guymer, E. A. W. Marien, J. M. Muir, G. H. G. Southwell-Sander.

D.M.R-D.—Joseph Ainsworth, Hussain Syed Ali, Ahmed Harold Ansári, E. B. Bradbury, T. D. Brick, J. B. Chetwynd, W. R. Cole, Stanley Davis, W. H. Dempster, J. R. Dow, Dineschandra Dowera, E. P. G. H. du Boulay, Prasanta Kamal Dutt, E. R. Edmunds, J. T. Furnival, D. M. Gregg, C. I. Griffiths, H. J. Hagger, G. K. E. Inman, N. R. Jefferson, J. V. Kent, A. H. McCallum, Ambat Narayanan Kutti Menon, Gordon Osborne, Mohammad Ramzan, K. G. Reynolds, P. W. E. Sheldon, B. S. H. Storr, John Sutcliffe, D. K. M. Toye, Keshawrao Shankerrao Warang, Krystyna Wowkonowicz.

D.M.R-T.—W. R. Argument, R. J. Dickson, Ambalal Mohanlal [illegible] Kinsella, William Kulke, Marcus [illegible] Walton.

[illegible] al Ela, Nasiruddin Ahmad, A. J. E. [illegible] Raman Das Gupta, W. R. Denny, [illegible] an, W. G. L. Hood, D. G. Jones, J. I. Kelly, P. J. O. McCullen, [illegible] Madan, Wilayt Ali Malik, H. M. Parsons, C. H. [illegible] Ryan, Dharam Vir Sethi, Stanislas Silberm [illegible] erenda, J. D. Trethowan.

D.P.M.—L. D. Gardner, Aaron Gillis, Delfan Lewis, W. V. Livingston, I. H. Martin, H. F. Osmond, Leslie Sohn.

D.T.M. & H.—W. E. Barnes, Amiya Kumar Basu, D. E. Boye-Johnson, C. F. Egan, S. C. Ferguson, M. M. Lewis, Champaklal Pranlal Nanavati, D. W. Quantrill, Hardeo Narain Singh.

Medical War Relief Fund

Last year 27 awards were made, 19 as gifts and 8 as loans. In all £3500 was distributed, £3000 less than for the previous year. Help was given to doctors who had difficulty in re-establishing themselves after demobilisation, and to widows, usually in the form of grants for the education of children. A substantial balance remains in the fund, and the committee thinks it unnecessary, for the time being at least, to seek further contributions. Dr. E. A. Gregg has been elected its chairman in succession to Dr. H. Guy Dain.

Royal Faculty of Physicians and Surgeons of

At a meeting of the faculty on Jan. 9 with Dr. W. grass, the president, in the chair, Ramanlal Amrit was admitted a fellow of faculty *qua* surgeon.

Kent Pædiatric Society

A meeting of this society will be held at the Co Approved School, Godstone, Surrey, on Feb. 1, at 2.

Oxford Regional Hospital Board

Dr. A. Q. Wells is resigning from the chairman membership of the board so that he may have m for his research work at the University of Oxford.

London County Medical Society

The following officers have been elected: presider Matheson ; vice-president, Dr. L. T. Hilliard ; hon. Dr. C. H. Comerford ; hon. secretary, Mr. J. Gabe, St. Hospital, Greenwich, S.E.10.

Royal Australasian College of Surgeons

Grayton Brown, H. H. Eddey, R. S. Lawson MacMahon, and K. W. Starr, who are Hallett prize and fellows of the college, have endowed a prize va 5 guineas for the primary examination for fellowshi college, to be known as the Gordon-Taylor prize.

Medical Section of the Library Association

The following officers have been appointed fo chairman, Mr. W. R. Le Fanu (Royal College of of England) ; honorary secretary-treasurer, Mr. W. (Wellcome Historical Medical Library) ; honorary manager, Mr. F. N. L. Poynter (Wellcome Historica Library) ; other members of the committee, Mr. C. C. (London School of Hygiene and Tropical Medicine), Hopkins (British Dental Association), Mr. A. E. S. (Bristol University Medical Library), and Mr. (Royal Society of Medicine).

Chadwick Lectures

On Tuesday, Feb. 14, at 26, Portland Place, Lond Dr. C. Banning, chief medical officer of public he Gravenhage, Holland, will speak on Coördination the Public-health Service and Private Enterprise in On Tuesday, March 14, at Westminster Hospital School, Horseferry Road, S.W.1, Dr. C. A. Bou speak on the Maintenance of Health by the Prev Accidents in the Home. Both lectures will take 2.30 P.M. Further particulars may be had from the of the Chadwick Trust, 204, Abbey House, Wes S.W.1.

Science To-Day is now appearing in a ne This journal, which is published weekly, is obtaina 35*s.* per annum, from Weekly Science Newslett 104, Clifton Hill, London, N.W.8.

Medical research in the Colonial Service has been in an official booklet entitled a Note on Some of the Studies Undertaken by Members of the Colonial Service during the period 1930–47, with a Bib (H.M. Stationery Office. Pp. 47. 1*s.*).

Appointments

BARLEY, D. A., M.B. Lond., F.R.C.S., D.L.O. : consultant and throat surgeon in the Plymouth clinical area.

FINKLEMAN, BENEDICT, M.D., M.SC. Manc., D.P.M. : medic tendent, Rainhill Hospital.

KENNARD, H. W. H., B.A., M.B. Camb. : consultant p Salisbury group of hospitals.

LAWSON, MARY, M.B. Belf., D.P.H. : asst. M.O., school m child-welfare departments, Rochdale.

MCPHERSON, A. G., M.CHIR. Camb., F.R.C.S. : consulta in Bristol clinical area.

NAISH, J. M., M.A., M.D. Camb., M.R.C.P. : consultant ph Bristol clinical area.

NUSSBAUM, ILSE, Staatsexamen Berlin, D.P.M. : consul resident psychiatrist (whole-time), Rainhill Hospital.

RAWLINSON, M. P. G., M.A. Camb., M.R.C.S., D.P.H. : M.O. health district, Alberta, Canada.

SWERDLOW, MARK, M.B., B.SC. Manc., D.A. : consultant a hospitals predominantly in St. Helens and Warringto

Hospital for Sick Children, Great Ormond Street, London

BASSETT, H. F. M., M.B. Lond. : house-surgeon.

FISHER, O. D., M.B., M.R.C.P., D.C.H. : medical reg. pathologist (senior registrar grade).

JACKSON, A. D. M., M.B. Lond., M.R.C.P., D.C.H. : house

JOLLY, H. R., M.A., M.B. Camb., M.R.C.P., D.C.H. : medica and pathologist (senior registrar grade).

LANGHAM, J. M., M.B. N.Z., F.R.C.S. : house-surgeon.

LEVEAUX, V. M., M.D. Lond., M.R.C.P. : house-physicia

TREATMENT OF LEPROSY WITH DIAMINO-DIPHENYL SULPHONE BY MOUTH

JOHN LOWE
M.D. Birm., M.R.C.P.
IRECTOR, LEPROSY RESEARCH UNIT, NIGERIAN LEPROSY SERVICE, UZUAKOLI, NIGERIA

Diamino-diphenyl sulphone (D.A.D.P.S.) was the first ulphone synthesised (Fromm and Wittmann 1908), but s pharmacology and therapeutic effects were not tudied until 1937, when Buttle et al. found that t possessed remarkable properties. In streptococcal nfections in mice, doses of 0·4 mg. were as effective s doses of sulphanilamide a hundred times greater; nd doses of 0·04 mg. were only slightly less effective than ·4 mg. In protection tests, 2 mg. gave better results than 50 mg. of sulphanilamide. Its acute toxicity was however ten to twenty times greater than that of sulphanilamide.

Also in mice, Bauer and Rosenthal (1938) reported similar findings. Buttle et al. (1937) also studied the effects of D.A.D.P.S. in rabbits and in monkeys. In rabbits the results were less striking than in mice, but still very good. In monkeys, the antibacterial activity of the blood after a dose of 1 g. of D.A.D.P.S. was about the same as after 4 g. of sulphanilamide, and the effect was more lasting. Further work in other animals followed, and D.A.D.P.S. later became established as a powerful antibacterial agent in veterinary medicine (McEwen et al. 1941, Francis 1947).

In man, Buttle et al. (1937) found that after a single dose of 300 mg. the blood had definite antibacterial properties, but no detailed studies were reported. Subsequently (Buttle, personal communication) a therapeutic trial was made in human beings with acute infections; doses of the order of 1–2 g. a day were given, but, because of the rapid production of methæmoglobinæmia and other toxic effects, the treatment was soon abandoned. The only other information available to me on the toxicity of D.A.D.P.S. in man is a statement made by Long and Bliss in 1939 and quoted by Feldman et al. (1944) that D.A.D.P.S. was considered too toxic for use in man.

There seem to have been no attempts to determine the therapeutic blood-level needed in man or the dosage necessary to produce that level. The little work that was done in man was with doses fixed arbitrarily at a level now believed to have been far too high.

When Rist et al. (1940) demonstrated the action of sulphones in experimental tuberculosis in animals, D.A.D.P.S., 'Promin,' and 'Diasone' were used in the extensive animal experiments which followed; D.A.D.P.S. showed up well, producing some results comparable to those of other sulphones in higher doses. In this work Feldman and his collaborators were prominent. Feldman (1946), in summarising the work, made no statement regarding the relative efficacy of the different sulphones. It is worthy of note that Smith et al. (1942) found that in vitro D.A.D.P.S. was ten times as active as promin.

In the trials of sulphones in human tuberculosis, because of its reputed toxicity to man no attempt seems to have been made to use D.A.D.P.S., possibly the most potent sulphone. The results of sulphone treatment in human tuberculosis have been disappointing.

THE SULPHONES IN LEPROSY

This work, started in the United States in 1941 and continued since, has been well summarised by Faget (1947) and by Sharp and Payne (1948). Workers in the United States have reported that the results of sulphone treatment in leprosy are much superior to those of any previous form of treatment, though it has limitations. Workers in other countries are now reporting similarly. Some British and other workers have been rather critical of the new treatment, but the opinion has steadily gained ground that a great step forward in leprosy treatment has been made.

Practically all this work has been done with the relatively expensive and complex proprietary sulphones, promin, diasone, and lately 'Sulphetrone.' Until recently no attempt was made, once more because of its reputed toxicity, to use the simpler and cheaper D.A.D.P.S. Cochrane (1949) reports an attempt to use D.A.D.P.S. in leprosy, giving twice-weekly injections of 1·25 g., but he has found that toxic effects are too common and too serious to make this treatment widely applicable, though the results were good.

Some of the criticisms made of sulphone treatment in leprosy have been shown to have little foundation. Thus the statements that it is not tolerated by many patients, and that it is of value only in the severe "lepromatous" cases, have been proved wrong (Lowe and Smith 1949). But there are two criticisms which still carry weight—that in severe lepromatous cases the treatment takes such a very long time (four years or even more), and that the treatment is too costly for wide use in poor tropical countries.

The first criticism—the length of the treatment—carries little weight because of the still greater length of hydnocarpus-oil treatment in such cases, and there is also the severe discomfort of the many injections and the uncertainty of the response.

The second criticism—high cost—is the really potent one. A treatment which costs for drugs alone £10–15 a year per patient and may last five years is completely inapplicable on a large scale in the mostly poor tropical and subtropical countries where leprosy prevails. Moreover, it is among the poorer sections of the population that leprosy is most common. Sulphone treatment on its present basis can never be more than a treatment for the privileged few; the vast majority of those needing the treatment must go without it.

The expense of sulphone treatment could be usefully reduced if a much more efficient and rapidly acting sulphone could be found, or if the sulphones could be made much more cheaply. A sulphone which would be both cheaper and more effective would be of enormous value. This is why some leprosy workers are turning their attention to D.A.D.P.S., a non-proprietary drug which can be made cheaply. The question which this paper attempts to answer is: can it be used in treating human leprosy with safety and with good therapeutic effect?

MODE OF ACTION OF SULPHONES

The sulphones now in common use in leprosy—promin, diasone, and sulphetrone—are derivatives of D.A.D.P.S. Their mode of action seems to be similar to that of the sulphonamides. The question arises whether the more complex sulphones exert their antibacterial action in the form in which they are given or only when they are broken down to D.A.D.P.S. in the body. If the latter view is correct, where does this breakdown to D.A.D.P.S. mainly occur—in the gut before absorption, when the drug is given by mouth; or in the body fluids or cells after absorption from the gut or, in the case of injection, from the tissues?

Johnson (1940) studied the fate of promin after oral administration and after injection. He found that, after injection, nearly all could soon be recovered in the urine as free promin in the form in which it was injected, but that after oral administration only 30% appeared in the urine and some of it had undergone conjugation. These findings suggest (*a*) that promin undergoes a change to D.A.D.P.S. in the gut before or during absorption, (*b*) that much promin given by mouth is not absorbed at all, and (*c*) that after injection very little chemical change occurs and the production of D.A.D.P.S. after injection must be very small.

Hinshaw and Feldman (1941) found that while promin could be given intravenously in doses up to 15 g. with little or no toxic effect, a dose of 1–3 g. by mouth often produced cyanosis and other toxic effects.

Because of these findings, the intravenous injection of promin became a standard method of sulphone therapy. It seems possible, however, that intravenous injection, though much reducing toxicity, reduced therapeutic activity still more.

The administration of diasone has been mainly by mouth. Given in this way, doses of more than 2 g. a day are often toxic, as with promin. Observations made here (Smith 1949) indicate that after the oral administration of diasone, D.A.D.P.S. can be isolated from the urine, but most of the drug is excreted as diasone. It is not clear whether the breakdown to D.A.D.P.S. occurs in the gut, or in the body after absorption.

Regarding sulphetrone more information is available. Brownlee (1948) stated that when sulphetrone is given by mouth, 50% or more is absorbed; practically all the drug present in the body is present as sulphetrone, and it is rapidly excreted as such, mainly in the urine. The absence of acetylation and other forms of conjugation was held to imply that sulphetrone is not hydrolysed to D.A.D.P.S. On Brownlee's data the undoubted therapeutic activity of sulphetrone in leprosy must be attributed to the action of sulphetrone itself. Findings made here (Smith 1949) have not supported Brownlee's findings in some respects. The absorption from the gut is much lower than the 50% reported by Brownlee. While most of the sulphone excreted in the urine is in the form of sulphetrone, a small fraction is in the form of D.A.D.P.S. Even before these findings were published, Brownlee (personal communication) wrote: "It appears most likely to us that it is the rate of degradation (to D.A.D.P.S.) that is important; that is to say, that the lack of toxicity of sulphetrone could quite well be consistent with a slow hydrolysis to D.A.D.P.S." In a later personal communication Brownlee stated:

> "I have looked carefully into this matter again and can say that if sulphetrone is degraded to D.A.D.P.S. it must be degraded less than 10%.
>
> "Those who have studied systematic series of sulphones, such as Smith at Bethesda, have concluded that the amino group or groups must be free or potentially free to have antibacterial activity. Now sulphetrone is antibacterial in the test-tube and is chemotherapeutic in man. If these views are correct, then the micro-organism itself must degrade sulphetrone, after it passes through the cell wall, to D.A.D.P.S. We have tried to prove this point experimentally but have failed."

Thus, even according to Brownlee, who appeared to be the chief exponent of the opposite view, complex sulphones possibly or probably act by being hydrolysed to D.A.D.P.S., though, with some of the complex sulphones, the amount of this hydrolysis is very small.

This discussion brings us to the following important practical points. It is well-established by the experience of many workers that complex sulphones, given in doses producing a blood-concentration of the order of 5 mg. per 100 ml.—and often much less than this—are therapeutically active in leprosy. Most of this blood content is not degraded to D.A.D.P.S. and is therefore possibly or probably inactive. We must conclude that the minimum therapeutic blood-level of D.A.D.P.S. itself in leprosy is perhaps 1 mg. per 100 ml., or even less.

The question to be investigated is whether it is possible in man to produce blood-levels of D.A.D.P.S. of this order without toxic effects. The experiment outlined below was planned to answer this question.

PRELIMINARY TRIAL OF D.A.D.P.S. BY MOUTH

From October to December, 1948, nine patients with leprosy were given D.A.D.P.S. daily by mouth in small and slowly increasing doses, with careful clinical and laboratory examinations for signs of toxicity, and the blood-levels attained on different doses were estimated. The daily administration was continued for 9 weeks. The daily dose was given all at one time. The results are summarised below.

Period	*Daily dose (mg.)*	*Resultant blood-level (mg. per 100 ml.)*	*Toxic effects*
Weeks 1 and 2	100	<0·5	None
,, 3 and 4	200	0·5–0·8	None
,, 5 and 6	300	0·8–1·4	None
,, 7 and 8	400	1·0–1·8	Some increase in hæmolysis
Week 9	500	1·5–2·2	More hæmolysis Experiment stopped

These results were striking. The first dose of 100 mg. gave a definite blood reaction for sulphone, *though* the blood-level attained was hardly measurable. Further doses soon produced a measurable blood-level; and when the dose rose to 300 mg. a day the blood-level averaged slightly more than the 1 mg. per 100 ml. which, on the grounds outlined above, is probably a therapeutic level. Moreover, with administration once daily the blood-level remained constant throughout the day. The later stages of the experiment showed that we had a considerable margin of safety; the slight signs of toxicity at the highest dosage soon subsided when the drug was stopped.

The findings showed that with 300 mg. of D.A.D.P.S. a day the blood-level was comparable to that attained with doses of diasone or sulphetrone five to ten times greater. An explanation of this was sought, and pharmacological studies of the three sulphones were carried out here (Smith 1949). Balance experiments to study the absorption and excretion of sulphetrone, diasone, and D.A.D.P.S. at different dosages, each maintained for two weeks, gave the following results at all the dosages tested.

When sulphetrone was given by mouth over 80% of it was passed in the fæces and was thus apparently unabsorbed, while less than 20% appeared in the urine. The figures for diasone were much better, about 50% being passed in the fæces and about 50% in the urine. For D.A.D.P.S., however, the figures were much better still, less than 5% being passed in the fæces and over 85% in the urine. Thus the absorption of D.A.D.P.S. from the gut after oral administration is excellent, and this fact partly explains the blood-levels attained on such small doses. But of equal if not greater importance is the slow elimination of D.A.D.P.S., mainly by the kidneys. Whereas after ordinary therapeutic doses, when long treatment is stopped, sulphetrone blood-levels are not measurable after 3–4 days, and diasone blood-levels are not measurable after 6–7 days, blood-levels of D.A.D.P.S. are still measurable after 14 days, and traces are found for much longer periods.

Thus the low dosage of D.A.D.P.S. necessary to maintain what is theoretically a therapeutic blood-level in leprosy is explained by the almost complete absorption from the gut and the slow elimination by the kidneys. These facts also probably explain the toxic effects reported by Buttle et al. (1937) on doses of 1–2 g. The blood-level attained on this dosage in a few days must have been very high.

TRIAL OF D.A.D.P.S. IN HUMAN LEPROSY

Immediately after the preliminary experiment in the nine patients recorded above, a therapeutic trial on a considerable scale was instituted in December, 1948. Fifty patients with leprosy, mostly of the severe lepromatous type, were selected. Exactly the same régime was followed as in the preliminary experiment; the osage was 100 mg. a day for two weeks, 200 mg. a day or two weeks, and the standard dose of 300 mg. a day rom the fifth week onwards. To begin with, frequent æmoglobin and blood-sulphone estimations, Schlesinger ests, liver-function tests, and other checks for possible oxicity were in force. As the experiment progressed, he toxic effects were found to be minimal, and later ll routine tests of this nature were abandoned as nnecessary.

The number of patients treated with D.A.D.P.S. was lowly increased to nearly ninety. Treatment has now November, 1949) been almost continuous for nearly a ear (except for one small break of 2 weeks because of taffing difficulties). The general condition of the atients is excellent, and almost all show higher hæmoglobin values than when treatment was started. (All eceive 0·7 g. of ferrous sulphate in a mixture freshly prepared every day.) In not one single case have we seen he toxic effects—nausea, vomiting, hepatic pain, and aundice—reported by Cochrane (1949) after twice-weekly njections of 1·25 g. The experiment has thus amply proved the safety of oral administration of D.A.D.P.S. by the method here outlined, but, as noted before, the mportance of slow induction of the treatment cannot be over-stated. The considerable safety margin is shown by the fact that, in a small number of selected patients, the daily dose has since been slowly increased to 400 and 500 mg. a day and maintained at that level for months without toxic effects.

Results in Lepromatous Cases

The lepromatous cases treated with D.A.D.P.S. for 6 months or more now (November, 1949) number exactly fifty. This group was a very varied and representative one, including a considerable number of very severe nodular cases, some with complications such as leprous affections of the eye and of the respiratory passages; other cases, though lepromatous, were milder, with localised or diffuse lepromatous infiltration of skin and mucous membranes, with few or no complications.

The results on the whole have been the same as those recorded for sulphone treatment in general—slow but sure subsidence of activity of the leprous lesions, gradual shrinkage of leprous nodules and infiltrations, healing of lepromatous ulcers in skin and mucous membranes, and improvement in the patients' vigour and sense of well-being. This clinical response to D.A.D.P.S. has certainly been no slower and has possibly or even probably been quicker than the response seen in patients treated with sulphetrone or diasone, though it is too early to make dogmatic statements on this point.

Further, a diminution in the number of bacilli in the lesions, as shown in "slit smear" preparations made by standard methods, is already apparent in many of our cases. This is at least as great as the diminution we have seen in similar cases treated for a similar period with sulphetrone or diasone. Three cases have become bacteriologically negative. The results in our fifty lepromatous cases treated for 6–12 months, with an average duration of treatment of just over 9 months, are as follows: definite clinical improvement in 36 cases (72%); definite bacteriological improvement in 31 cases (62%); and no cases showing clinical or bacteriological deterioration. Febrile reactions (erythema nodosum) occurred in 15 cases (30%). The changes in bacteriological status were as follows:

Bacteriological status

Before treatment			*After treatment*		
Status		*No. of patients*	*Status*		*No. of patients*
4 +	..	16	4 +	..	7
3 +	..	10	3 +	..	9
2 +	..	19 (1 now neg.)	2 +	..	17
1 +	..	5 (2 now neg.)	1 +	..	14
Neg.	..	0	Neg.	..	3

The bacteriological status is determined as follows. *A number of microscopic slide "smears" are made from various sites in the body, examined and graded. 4 + indicates a preparation teeming with bacilli, thousands to a microscopic field. 1 + represents a smear in which bacilli are few and not easy to find. 3 + and 2 + are intermediate grades between 1 + and 4 +. In each patient the average figure recorded in several smear preparations from different parts of the body is taken to indicate the status of the patient.*

In assessing results clinical improvement is recorded only if it is very definite, and bacteriological improvement only if the reduction in bacilli is sufficient to down-grade the findings (e.g., from 4 + to 3 +). Such a down-grading probably indicates on the average a reduction in the number of bacilli found in smears to about a tenth of the previous number. Thus the estimates of improvement are very conservative.

The period of treatment of these patients is admittedly short; at least 2 years' treatment will be needed in such lepromatous cases before a reasonably accurate assessment can be made. The data so far do not justify a definite claim that D.A.D.P.S. is more rapidly effective than other sulphones in lepromatous cases, though the general impressions of the staff and patients suggest that this is so.

Results in "Tuberculoid" Cases

Until recently it was stated that this milder and often self-limiting, though frequently crippling and disfiguring, form of leprosy did not respond to sulphone treatment. The first published report indicating that it would respond was that of De Souza Lima (1948), though his statements on the subject are cautious and a little vague.

D.A.D.P.S. TREATMENT OF LEPROSY: "TUBERCULOID" CASES

Case no.	No. and diameter (inches) of skin lesions	Inflammation of skin lesion	Thickening, tenderness, and pain in nerves	Weeks before first visible response to treatment	Weeks before complete subsidence of skin activity	Total weeks of treatment to date	Persistence of nerve lesions
	Major Tuberculoid						
1	8 (1–2)	+++	+++	3	20	40	Tenderness gone; thickening less
2	12 (2–6)	+++	++	4	20	36	Nil
3	About 50 (1–2)	+++	—	3	12	36	Nil
4	About 20 (1–12) ..	+++	+	4	24	36	Some thickening; slight tenderness
5	About 24 (3–4)	+++	++	4	24	36	Some thickening; no tenderness
6	12 (3–6)	+++	+	3	24	24	" " " "
7	About 20 (½–3)	+++	+++	2	24	24	Ulnar neuritis still present
8	Over 50 (3–6) ..	+++	+	2	12	28	Some thickening; no tenderness
9	About 50 (½–3)	+++	+	4	16	20	Nil
10	About 10 (½–2) ..	+++	+++	2	20	20	Thickening less; no tenderness
11	Over 50 (1–3)	+++	++	4	still incomplete	16	" " " "
	Intermediate Tuberculoid						
12	Several hundred (small)	++	+	3	12	36	Nil
13	Innumerable (small) ..	++	+++	3	24	32	Thickening and tenderness almost gone
	Minor Tuberculoid						
14	Several hundred (small)	+	—	3	12	36	Nil
15	3 (½–3)	+	—	3	24	24	Nil

Elsewhere (Lowe and Smith 1949) we have recorded the rapid and even dramatic response of leprous lesions of this type to sulphone treatment; focal changes in the skin patches are seen within a few weeks, and activity usually subsides completely within 6 months, though the inflammation of nerve-trunks takes longer to subside. (A fuller report is being prepared.)

The accompanying table summarises the results in fifteen such cases treated with D.A.D.P.S. It will be noted that a response was seen in the lesions within a month, and sometimes within a fortnight, of treatment being started, when the dose was still 200 mg. or even 100 mg. a day. There are here definite indications that D.A.D.P.S. acts more quickly than other sulphones. Moreover, activity, inflammation, and thickening of the patches in the skin have tended to subside completely in a shorter time than with other sulphones. In one case, in which treatment was stopped after 6 weeks because of sulphone dermatitis, the subsidence of activity of the lesions has been continuous and is now complete. It is obvious that quite a short period of treatment is enough to arrest the skin lesions.

In some of these patients treatment has been given for only a few months, but its effect on the thickening and inflammation of the nerves is already apparent in most cases. In only three cases are nerves still abnormally tender; many still show nerves that are hard, thick, and fibrotic, but in others the nerve thickening is much less than it was. In none has the neuritis been aggravated by sulphone treatment—a surprising thing considering how often painful "reactions" in nerves arise in lepromatous cases under treatment.

Thus the results of D.A.D.P.S. treatment in "tuberculoid" leprosy have been highly satisfactory—at least as good as and probably better than the striking results seen with other sulphones used here.

PRACTICAL ASPECTS OF D.A.D.P.S. TREATMENT

Difficulties

The difficulties encountered in establishing and maintaining D.A.D.P.S. treatment are not serious; they are of the same kind as are experienced with more complex sulphones, though probably milder.

The incidence of *febrile reactions* (erythema nodosum) in lepromatous cases has been 30%; this is almost exactly the same incidence as with sulphetrone, and the severity and duration of these manifestations has been no greater than with sulphetrone. We suspend sulphone treatment until the condition has subsided.

Anæmia has been no more, and probably less, common or severe than with sulphetrone; a possible factor here is that sulphetrone forms an insoluble compound with iron in the gut (Brownlee 1948) and may thus prevent iron absorption. When D.A.D.P.S., with its much smaller dose, is used this factor may be absent or less active.

Leprous *neuritis* and leprous *eye inflammation* may be precipitated by D.A.D.P.S. in lepromatous cases, just as by the other sulphones, but they are no more common or severe. Once again we suspend treatment until acute symptoms have subsided.

A drug *dermatitis*, which may progress to exfoliation, may occur with D.A.D.P.S., as with other sulphones, between the 3rd and 5th weeks of treatment. Among nearly ninety patients treated with D.A.D.P.S. we have had three such cases; two however occurred among six patients in whom, as an experiment, the dose has been increased at twice the usual rate. Only one case of dermatitis has been seen in over eighty cases treated under our normal régime. The dermatitis subsides on the cessation of treatment and the oral administration of anti-histamine drugs; we have used 'Anthisan.' In these cases sulphone treatment must be withheld for at least 2 months, and often it can be resumed only after the patient has been desensitised with repeated small and increasing doses; these are best given by injection, working up from 2 mg. or even lower levels if necessary. In sensitised patients dermatitis may appear within few hours of administration, so daily injections ar recommended for desensitisation.

Intercurrent *bacterial infections* during sulphone therap are not common, but when they do occur they are unlikel to respond to sulphonamides. This is probably becaus the ranges of activity of sulphones and of sulphonamide overlap widely; organisms resistant to sulphones ar likely to be sulphonamide-resistant. For this reaso penicillin plays an important part in the treatment o intercurrent disease in sulphone-treated patients. Her the commonest conditions requiring penicillin therap are pneumonia and "tropical" myositis. In patient under sulphone therapy the ordinary septic complication of leprosy rarely arise, presumably because of the wid range of activity of the sulphones.

Cost

The price of 100 mg. tablets of D.A.D.P.S. is 14*s.* a thousand. *A patient treated by the method* here outlined will require on the average a thousand tablets year, so the cost will be 14*s.* a year for drugs. The cos of treating one patient with diasone or sulphetrone i at present £10–15 a year. Thus the use of D.A.D.P.S. ha reduced the cost of sulphone treatment to about twentieth of the previous figure.

In Nigeria, treatment with hydnocarpus oil is now n cheaper than with D.A.D.P.S., and in addition to the o there is the big expense in syringes, needles, sterilisatio and staff to give the injections. Moreover, the results a greatly inferior.

Financial considerations now prevent the wide u of the complex proprietary sulphones, but with D.A.D.P. it should be possible to treat all the thousands of cas of active leprosy in the Nigerian leprosy institutions. other countries the same factors will operate in varyi degrees.

Possible Modifications

Our present régime is based on a standard dose 300 mg. given once a day. The question arises wheth daily doses are necessary. A small group of cases being treated with twice-weekly doses given by mout the régime being: 1st week, 100 mg. doses; 2nd wee 200 mg. doses; and so on to 500 mg. doses in the 5t week, this dose being then maintained. The blood-level range from 2 mg. per 100 ml. soon after the dose t 0·3 mg. just before the next dose. Toxic effects are no serious, and clinical improvement is beginning to appea Injections seem quite unnecessary for twice-weekl treatment. Such a régime would be suitable for ou patients, and would reduce the cost of treatment to 7 a year.

A further question is whether, on daily administratio a dose of 300 mg. a day is necessary or advisable. Th will be investigated later. We already know that, i tuberculoid cases, daily doses of 100 mg. are therapeuti ally active, but in these patients bacilli are very few an natural resistance is high. It would therefore be wron to argue that 100 mg. a day is sufficient for heavi infective lepromatous cases with no natural resistanc Nevertheless, there are indications that improvement not proportional to the size of the dose. Our patients o 400 and 500 mg. a day are not so far showing an apprec ably more rapid improvement than those on lower doses but the period of treatment is too short for a soun judgment. The best standard dose may turn out to b less than our present 300 mg.; and if so the cost treatment will be still further reduced.

Requisites

The main and in fact the only real necessity f D.A.D.P.S. treatment is the supervision of a soun clinician who knows his leprosy. Proper clinical exam nation before and during treatment, and the regulatio f treatment according to the findings, are all that is eally needed. During the first few weeks of treatment a veekly examination is advisable; later, an examination ortnightly, monthly, or even less frequently may suffice rovided the patient can refer to the physician at once f need arises. A few beds for temporary admissions luring "reactions" are very useful.

The giving of the proper doses must be adequately upervised. Primitive people often think that they annot have too much of a good thing. A big dose of D.A.D.P.S., particularly in the early phases of treatment, may be dangerous. Moreover, a patient may be tempted to keep and sell some of his tablets instead of swallowing them.

Laboratory facilities can be very simple. To judge the results of treatment accurately, microscopical examination of "smears" is of course necessary. Hæmoglobin estimations are useful, but the good physician will detect anæmia clinically. The Schlesinger test for urobilin in the urine is useful in cases of suspected toxicity, for the test with Ehrlich's reagent does not work when sulphones are present in the urine. The results must be interpreted with care, for disordered liver function and a positive Schlesinger test are common in "normal" Africans. Blood-sulphone estimations are unnecessary as a routine measure, though they can easily be done with the Lovibond comparator and they add to the value and interest of the work from the physician's standpoint.

DISCUSSION

The introduction of the sulphone treatment by workers in the U.S.A. began a revolution in the treatment of leprosy, whose magnitude is only now becoming apparent and is little realised in the United Kingdom, where publications have been few and opinion has been divided; for while Muir (1947, 1948) and Davey (1948) have written enthusiastically of the treatment, Cochrane (1947), Rogers (1948), and THE LANCET (1948) have been more critical. Cochrane, in later publications in specialist journals (1948, 1949), has shown increasing interest in and enthusiasm for sulphone treatment, his latest report being on 54 treated lepromatous cases, all of which have improved, some markedly, ten of them becoming bacteriologically free of infection.

The number of sulphone-treated cases reported on by British workers has been small, usually less than fifty, and the period of treatment has usually been only a few months, though the 54 cases reported by Cochrane (1949) have been treated for 2½ years. Here at Uzuakoli, Nigeria, the number of cases treated (first by Davey and later by Lowe) has been over 350, and the period of treatment has been up to nearly 4 years; the evidence of the great value of the treatment has been overwhelming (Lowe and Smith 1949).

In 20 years' experience of treatment with hydnocarpus oil and its derivatives, with a growing appreciation of the frequently self-limiting nature of leprosy, I gradually became more and more sceptical of the specific value of this treatment. It often produces clinical improvement in the milder cases, particularly tuberculoid cases, and it accelerates the strong tendency to spontaneous arrest. In mild lepromatous cases it sometimes produces apparent arrest of the disease, but its action is very uncertain, and relapse is common. In lepromatous cases in general, particularly the severer ones, the ability of hydnocarpus oil to modify the course of the disease is often very limited. Years of painful treatment often accomplished little. The argument advanced by some that hydnocarpus treatment is of value because it prevents the tuberculoid cases from becoming lepromatous is negatived by the finding that even without treatment this change is very rare.

The change in outlook produced by sulphone treatment is one of the most striking achievements of modern medicine. The full action of sulphone treatment in severe cases is very slow but amazingly certain. The physician can now feel absolute confidence that an active case of leprosy, no matter how severe, will respond to sulphone treatment; that the disease will cease to progress from the time when the treatment is begun; and that the lesions already present will slowly subside and the infection gradually die out.

The use of D.A.D.P.S. has certainly overcome the difficulty of the cost of sulphone treatment. Whether its use will reduce the duration of treatment remains to be seen. It has at any rate made sulphone treatment possible for a vast number of patients in tropical countries, whereas previous forms of sulphone treatment could not be more than the privilege of the few.

The question arises whether the findings here recorded may not have an important bearing on the sulphone treatment of tuberculosis. So far, in human beings, this has been rather disappointing. Only the complex sulphones have been used. Since D.A.D.P.S. appears to be the most active of the sulphones and can be safely used in man, it may be of value in human tuberculosis. Its value in experimental tuberculosis has already been demonstrated, but its reputed toxicity has prevented its use in the human disease. A few preliminary observations made here have shown that D.A.D.P.S. is well tolerated by patients with tuberculosis of the lungs, and a proper trial is well worthy of consideration.

SUMMARY AND CONCLUSIONS

The special properties of D.A.D.P.S. are outlined. In vitro and in animals its antibacterial power is possibly the greatest of any of the sulphones.

The accepted idea that D.A.D.P.S. is too toxic for use in human beings is examined and found to be erroneous.

A régime of oral administration of small doses, rising very slowly from 100 mg. a day to the standard 300 mg. a day in 5 weeks, is recommended, treatment being continuous. This régime does not produce toxic effects of any consequence, and it will maintain a blood-level of about 1 mg. per 100 ml., which on theoretical grounds should be a therapeutic level in leprosy.

The almost complete absorption from the gut and slow elimination by the kidney explain the relatively high blood-levels attained with such small doses, and also explain the toxic effects reported with the much higher doses used by others.

In the avoidance of toxic effects, very slow induction of D.A.D.P.S. treatment is of paramount importance.

A therapeutic trial of this treatment in 88 patients with leprosy for periods up to a year is described.

Of the fifty lepromatous cases treated for more than 6 months, none show deterioration; 72% show clinical improvement; 62% show bacteriological improvement; and three have become bacteriologically negative. These results compare very favourably with those seen here with complex proprietary sulphones. There are indications that D.A.D.P.S. is acting more rapidly than these other sulphones.

In fifteen "tuberculoid" cases treated for 4–10 months the response has been apparent within a month, and sometimes within a fortnight or less, with complete subsidence of activity of the skin lesions within 6 months; the nerve involvement however takes longer to subside. The results, though similar to, appear to be more rapid than those seen with other sulphones in similar cases.

The cost of D.A.D.P.S. for the treatment for one patient for a year on this basis is 14s. The cost of treatment with the complex proprietary sulphones is about twenty times as much.

A régime for twice-weekly administration of D.A.D.P.S. by mouth suitable for outpatients is outlined, the cost being 7s. a year per patient. Injections seem to be unnecessary.

It is suggested that the more complex sulphones act by being hydrolysed to D.A.D.P.S. in the body. They are incompletely absorbed from the gut and incompletely hydrolysed to D.A.D.P.S.; they thus provide an unnecessarily elaborate and expensive method of securing the action of D.A.D.P.S. in the body. Administration by injection, by preventing hydrolysis in the gut, may even reduce their therapeutic activity.

The administration of D.A.D.P.S. itself by mouth is safe, simple, and very cheap. It seems to be the most rational form of sulphone treatment.

Reconsideration of the sulphone treatment of human tuberculosis may be advisable in the light of the findings recorded here. Preliminary observations show that D.A.D.P.S. treatment as here outlined is well tolerated by patients with tuberculosis of the lungs.

The observations reported formed part of the work of the Leprosy Research Unit working first under the British Empire Leprosy Relief Association and now under the Nigerian Government..

My thanks are due to Dr. G. B. Walker, Director of Medical Services, Nigeria, and Dr. R. Bland, Senior Leprosy Officer, for their encouragement and for permission to publish this paper; to Dr. T. F. Davey, superintendent of the Uzuakoli Leper Settlement, for his willing help in arranging for the work; to Mr. M. Smith, B.SC., until recently of this unit, for the chemical work here reported and for supervising the work during my absence on leave; to Imperial Chemical (Pharmaceuticals) Ltd. for free supplies of tablets of D.A.D.P.S.; to Mr. John Francis, M.R.C.V.S., for a copy of his unpublished memorandum on sulphones, which has proved most useful in writing this paper; to Mr. G. Brownlee, PH.D., of the Wellcome Physiological Research Laboratories, for information, suggestions, and criticism; and to my African staff, particularly Mr. Okezie, technical assistant in the laboratory service, for valuable assistance.

Above all, my thanks are due to Dr. E. Muir, C.M.G., for the original suggestion that I should experiment with D.A.D.P.S., and to my African patients whose splendid coöperation enabled me to carry out his suggestion.

"... It is easy for hospital people to think in terms of the hospital as an institution, for public health people to think in terms of their highly standardized program, for physicians to think as entrepreneurs. It is harder for any of these three groups to think freely about what people need and how it can be made available to them ... is it possible that the accepted reasons for taking a sick person from his home and putting him in a hospital bed should be reexamined, and that if the hospital beds we have were used more judiciously we should not need so many more of them?"—*Annual report of the Commonwealth Fund*, 1949.

OBSERVATIONS ON CHLORAMPHE

J. D. GRAY
M.D. McGill
PATHOLOGIST, BELGRAVE HOSPITAL FOR CHILDREN AN
EYE HOSPITAL (KING'S COLLEGE HOSPITAL GROUP),

It has been shown that chloramphenicol (' mycetin ') exhibits antibiotic activity against *H. p* in a concentration of about 0·2 µg. per ml. in te experiments (Smith et al. 1948). Using the pap method on Bordet-Gengou medium, a 1 mm. z inhibition at a concentration of 0·25 µg. per m demonstrated against *H. pertussis* in this labora with the same method *H. parapertussis* gave a z 1·5 mm. at 2 µg. per ml.

However, a laboratory antibiotic effect cannot al be translated into terms of clinical usefulness, w depends not on the changes that can be demonstr on a medium but on whether the drug can cure a dis flourishing in the body. Consequently when an epide of whooping-cough presented itself during the sp and early summer of 1949, the opportunity was t to bring the disease and the antibiotic together an follow the outcome. There is no need to emph the importance of examining any drug which m exert a favourable influence in pertussis and lesse attendant train of misery.

It was not intended to report on the effect of chlor phenicol in this disease until a reasonable numbe cases had been collected. Experience has shown t conclusions drawn from trials in a small series in infective illnesses of childhood are often errone partly because of the protean nature of these disea However, during the investigation some factual inf mation concerning chloramphenicol was gathered wh seemed likely to affect the future use of the drug a should therefore be recorded. Since the experime arose logically in the course of the work on whoopi cough it was difficult to split the clinical from t experimental findings without blurring the origins the latter and it seemed simpler therefore to repo the whole.

SELECTION OF CASES

The diagnostic criteria for accepting a case as a contr or for treatment were as follows:

(1) The isolation of *H. pertussis* from a postnasal swab using Lacey's modified medium and technique.

(2) The production of a paroxysmal cough during th examination period. (Swabbing the nose usually precipitate a paroxysm.)

(3) A normal erythrocyte-sedimentation rate (E.S.R.).

(4) An absolute lymphocytosis.

As the disease progresses it becomes increasingly difficult to isolate the organism, so some cases were accepted which met only the second, third, and fourth conditions.

In evaluating the effect of chloramphenicol in pertussi there is only one question to answer: What happens to the cough? Therefore the results were based on serial cough-counts made over twenty-four hours by the mother—usually from 2 P.M. on one day to 2 P.M. on the next. These were written on slips of paper to be presented when the patient was next seen. The mothers were not asked to differentiate between the types of paroxysms, but to note the total number of coughing attacks, irrespective of whether they were major, minor, or minimal. As far as possible, leading questions were avoided, and it was hoped that information on qualitative changes might be gleaned from spontaneous remarks made by the observers. The controls were given milk-sugar capsules which closely resembled those of chloramphenicol, and the number and spacing of the capsules were the same for treated and controls.

For the purpose of reporting the results, the series has been split into two groups—(A) cases which from the history might reasonably be placed in the first two weeks of the disease; and (B) those which on the same grounds could be placed in the third or fourth week. No case in the fifth or later week was included, because of the obvious difficulty of differentiating between a natural cure and a chemotherapeutic one late in the disease. There must be some overlapping of the groups, but in graphing the results this has been disregarded for the sake of clarity.

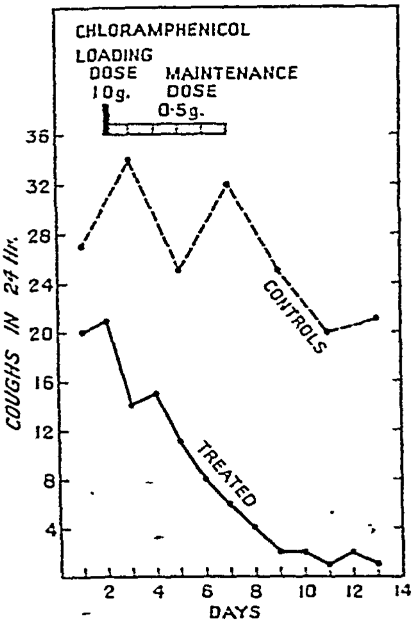

Fig. 1—Mean daily cough-counts in group A (first two weeks). Here and elsewhere the initial (loading) dose is shown in black and the maintenance dosage (g. per day) as a stippled oblong.

DOSAGE

No information regarding the optimum dosage was obtainable, so the early stages of the trial were used in an attempt to determine this. As a starting-point the dosage for typhoid fever was accepted—50–60 mg. per kg. of body-weight for loading, followed by 0·25 g. three-hourly for maintenance. Experience suggested that the loading dose was too small and the maintenance dose too fixed. The dosage finally decided on was as follows:

Up to the age of 1 year: 100 mg. per kg. followed by 60 mg. three-hourly.

From 1 to 3 years: 100 mg. per kg. followed by 125 mg. three-hourly.

Over 3 years: 100 mg. per kg. followed by 250 mg. three-hourly.

RESULTS

The following two cases are examples of group A (first two weeks) and group B (third or fourth week).

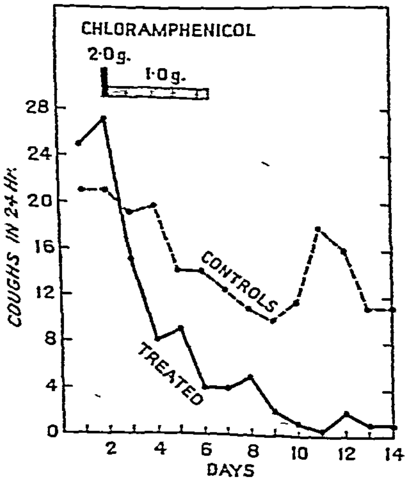

Fig. 2—Mean daily cough-counts in group B (third or fourth week).

Case 1.—Girl, aged $3^1/_2$ months, weight 5·5 kg. Cough started on Oct. 1, 1949. When first seen on Oct. 5 her cough was spasmodic in type, but there was no whooping or vomiting. She was having 4–5 spasms a day. White-cell count 9375 per c.mm. (polymorphs 38%, lymphocytes 60%, monocytes 1%, eosinophils 1%, basophils 0). E.S.R. 3 mm. in 1 hour (Crista). From the nasal swab taken on that day *H. pertussis* was isolated after two days incubation.

Oct. 6.—9 coughs in counting period. Still no major paroxysms.

Oct. 7.—Chloramphenicol 0·6 g. given as loading dose, followed by 60 mg. three-hourly.

Oct. 8.—6 coughs in counting period. Continue at 60 mg. three-hourly.

Oct. 9.—3 coughs in counting period. The coughs started to loosen "as if she had bronchitis." Continue maintenance dosage.

Oct. 10.—1 cough in counting period. White-cell count 13,750 per c.mm. (polymorphs 56%, lymphocytes 42%, monocytes 0, eosinophils 2%, basophils 0).

Oct. 11.—Chloramphenicol stopped.

Oct. 13.—3 loose minor coughs a day. Baby eating and sleeping well.

Oct. 16.—Nil to report. Told to return if there was any suggestion of a relapse.

The chloramphenicol was given to this baby in the form of a loose powder washed down with milk.

Case 2.—Girl, aged 6 years, weight 28 kg. Started dry hacking cough about Sept. 5, 1949. When first seen, on Sept. 19, she was vomiting and whooping in the paroxysms. Appetite poor, not irritable. White-cell count 12,800 per c.mm. (polymorphs 39%, lymphocytes 50%, monocytes 4%, eosinophils 7%, basophils 0). E.S.R. 5 mm. in 1 hour (Wintrobe). From nasal swab taken on that day *H. pertussis* was isolated after two days' incubation.

Sept. 20.—25 paroxysms in counting period.

Sept. 21.—Chloramphenicol 2·8 g. given as loading dose, followed by 250 mg. three-hourly.

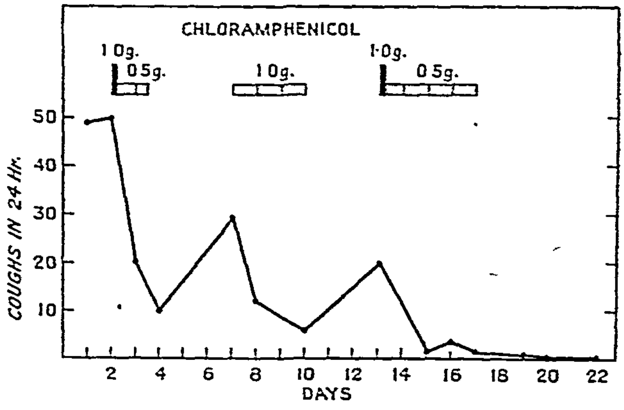

Fig. 3—Effects of insufficient dosage illustrated by three courses in child aged 8 months, weighing 10 kg., starting at fourteenth day of disease.

Sept. 22.—22 loose coughs, "like bronchitis." Vomiting and whooping has stopped. Continue treatment.

Sept. 23.—5 coughs with 4 vomits in counting period. Continue treatment. White cell-count 14,800 c.mm. (polymorphs 53%, lymphocytes 40%, monocytes 1%, eosinophils 6%, basophils 0).

Sept. 24.—7 coughs with 2 whoops in counting period; no vomiting. Completed four days' treatment. Chloramphenicol stopped.

Sept. 25.—Only coughs now when excited. White-cell count 18,700 per c.mm. (polymorphs 56%, lymphocytes 42%, monocytes 2%, eosinophils 0, basophils 0).

Sept. 27.—Nil to report.

Oct. 3.—Nil to report.

This patient had a sterile upper respiratory tract for seven days after the first day of treatment.

Effect of Chloramphenicol on Cough

Fig. 1 shows the daily cough-counts of 7 treated children and 9 controls, all in group A (first two weeks of disease). The ages of the controls were: 9 mos., 2 yr., 3 yr., 3 yr., 4 yr., 5 yr., 5 yr., $5^1/_2$ yr., and 6 yr.

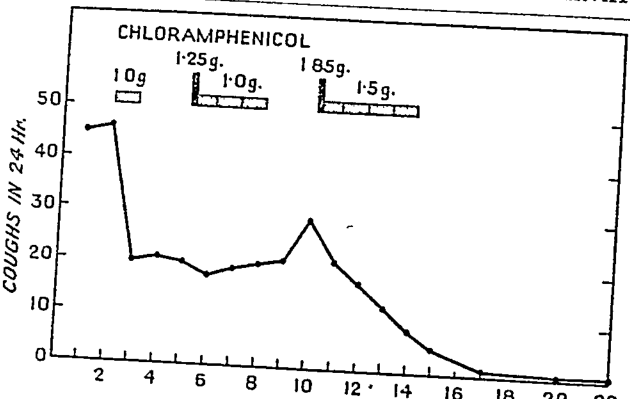

Fig. 4—Effects of insufficient dosage, illustrated by three courses in child aged 6½ years, weighing 18 kg., starting at seventh day of disease.

The ages of the treated children were: 7 mos., 8 mos., 9 mos., 4 yr., 5¾ yr., 6 yr., and 6½ yr.

Fig. 2 shows the daily cough-counts of 7 treated children and 8 controls, all in group B (third or fourth week). The ages of the controls were: 2 yr., 3 yr., 3 yr., 4 yr., 5 yr., 5 yr., 5½ yr., and 6 yr. The ages of the treated children were: 7 mos., 8 mos., 9 mos., 4 yr., 5¾ yr., 6 yr., and 6½ yr.

The qualitative changes in the coughs are reported by the mothers as follows. During the first twenty-four hours there is a reduction in the length of the paroxysms, usually with the abolition of either whooping or vomiting. After about seventy-two hours the hard hacking cough changes to a soft exudative one, described by some mothers as a "wet bronchitis." It is then claimed that the total cough-count drops to 3–5 per day.

Effect of Suboptimal Dosage

Fig. 3 demonstrates the effects of inadequate dosage on the cough-counts. In the first course the dosage was correct but the maintenance was too short. In the second no loading dose was given, and treatment was ineffectual in spite of a doubled maintenance dosage. In the third the dosage was correct.

Fig. 4 is another demonstration of inadequate dosage. In the first course no loading dose was given. In the second the loading dose was insufficient and the maintenance dosage too low. In the third the dosage was correct.

In several cases peculiar relapses were seen. These occurred after the correct loading and maintenance dosage had been given but the maintenance dosage had been continued for only three days. The paroxysms appeared to come under control, and the relief lasted for about four days, but then a recrudescence of the illness was reported in which the paroxysms approached the pretreatment level in both quality and quantity. This state lasted for three to five days, after which period, though no more chloramphenicol was given, the coughing rapidly lessened to the level attained at the end of treatment.

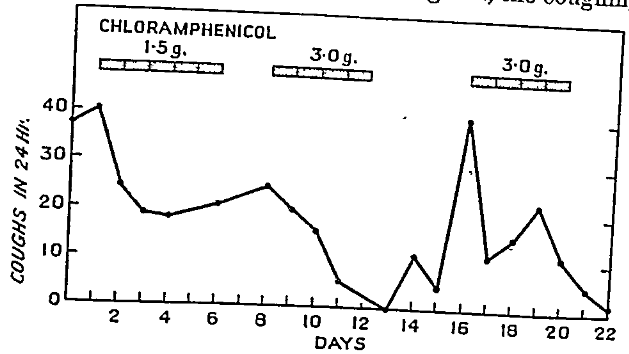

Fig. 5—Effect of rectal administration in child aged 1½ years weighing 10 kg., starting at fourteenth day of disease.

Plasma-levels

Chloramphenicol levels, estimated at varying times during treatment, ranged from about 48 μg. per ml. about three hours after a loading dose to 8–16 μg. per ml. during maintenance dosage. The levels were measured by diluting plasma with glucose-phenol-red broth at 1 : 2, 1 : 3, 1 : 4, 1 : 6, 1 : 8, 1 : 12, 1 : 16, 1 : 24, &c. The diluted plasma was inoculated with a *Shigella sonnei* having a known sensitivity of 2 μg. per ml. The end-point was taken at the first tube which did not sh fermentation. It must be emphasised that the end-poi accepted was that of the bacteriocidal value. Througho this work, bacteriostasis as a means of measureme has not been used. More recently, however, t chemical method of estimating chloramphenicol (Glazk 1949) has been in use and has given more accurat results.

Administration: Rectal Dosage

The administration of chloramphenicol by mouth t children aged 1–3 years presents a problem. At thi age children refuse to swallow capsules and it is futile to attempt to introduce the drug in powder form. Chloramphenicol has the most intensely bitter taste that ever offended a palate. It cannot be disguised in any of the vehicles hitherto used to deceive the taste buds. Babies will accept the powder diluted in a little milk or sugar water, presumably because they have not yet gained discrimination. Older children will coöperate but for the "in-betweens" treatment by mouth is ofte impossible. Obviously if chloramphenicol is essenti for the control of a grave infection it will have to b given by stomach-tube until some other method administration has been devised.

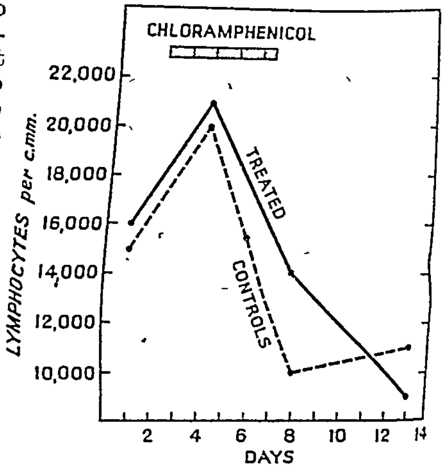

Fig. 6—Mean absolute lymphocyte-counts in group A.

Rectal administration was tried in 5 cases. Th chloramphenicol was given in two forms—(1) i cocoa-butter suppositories, each containing 1 g. o chloramphenicol; and (2) in gelatin capsules containing the required dosage, pierced with a needle in half a dozen places and then inserted into the rectum. The cocoa-butter suppositories were a failure. In 2 cases 18–24 g. of chloramphenicol in this form was given over a period of three days, with no appreciable effect on the disease. Fig. 5 shows the cough-counts in a patient receiving chloramphenicol by rectum in pierced capsules. The oral dosage required in this case would have been 1 g. for loading and then 1 g. daily in divided doses for five days. It has been suggested that to achieve comparable results with rectal administration the dosage must be 25% higher than the oral dosage. On that basis this patient should have been given about 1·25 g. for loading and then 1·25 g. daily for five days—i.e., a total of 7·5 g. It will be seen that in fact a total of 33 g. of the antibiotic was given per rectum in fourteen and a half days with disappointing results.

Effect on Lymphocytosis

Serial blood-counts were done in the treated children and controls to determine whether the lymphocytosis which nearly always accompanies whooping-cough could be influenced by chloramphenicol. In Fig. 6 the mean absolute lymphocyte-counts in 7 treated children and in 9 controls in group A (first two weeks) are compared. The hatched areas represent the approximate days of treatment. In fig. 7 there is a similar comparison between treated and controls in group B (third or fourth week). From these comparisons it appears that chloramphenicol does not affect the lymphocytosis of pertussis.

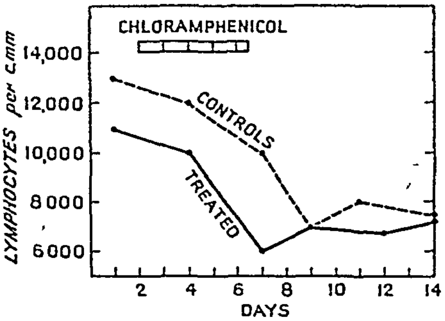

Fig. 7—Mean absolute lymphocyte-counts in group B.

Untoward Reactions

So far, 29 children have been treated for whooping-cough with varying doses of chloramphenicol in this inquiry. One child developed a reaction which seems worth describing in detail.

Case 3.—Girl, aged 5 years, weight 24 kg. First seen on Sept. 1, 1949. History of cough starting on Aug. 27, attacks worst at night. 13–14 coughs in twenty-four hours. No whooping or vomiting.

Sept. 2.—White-cell count 13,820 per c.mm. (polymorphs 41%, lymphocytes 48%, monocytes 1%, eosinophils 8%, basophils 2%). E.S.R. 8 mm. in 1st hour (Wintrobe).

Sept. 5.—*H. pertussis* isolated. Cough-count still 13–14 a day. Child irritable. No change in appetite.

Sept. 7.—27 coughs in counting period. Now whooping and vomiting.

Sept. 8.—32 coughs with whooping and vomiting. Chloramphenicol 2·4 g. statim, to be followed by 250 mg. four-hourly. At 4 P.M., the patient took the loading dose prescribed. By 5 P.M., her arms, chest, and face were covered with giant urticarial weals. Shortly afterwards she had an intense attack of asthma which led to cyanosis. By 8.30 P.M. she was beginning to improve, and when she was seen at 9.30 P.M. the attack was over. The chloramphenicol was stopped.

Sept. 11.—7 coughs in counting period. White-cell count 23,700 per c.mm. (polymorphs 31%, lymphocytes 65%, monocytes 1%, eosinophils 3%, basophils 0). *H. pertussis* not isolated. Patch test for sensitivity to chloramphenicol negative.

Sept. 14.—8 loose mucoid coughs in counting period. No night paroxysms.

Sept. 17.—7 short coughs in counting period.

Occasionally in the series the cough-count fell dramatically, as in case 3, after a single dose of chloramphenicol, but this is exceptional. The main point of interest in case 3 was the allergic reaction. It later transpired that this patient's mother had eczema as a child and now has periodical attacks of summer asthma, but as far as could be ascertained this was the patient's first attack of asthma or urticaria. Considering the time relationship, it seemed reasonable to conclude that the dose of chloramphenicol was the cause of the allergic reaction, though it was unlikely that the child could have been sensitive to the chloramphenicol molecule itself before this illness, since she could not possibly have had previous access to the antibiotic. The alternative explanation was that an antigen to which the patient was sensitive had been released by the action of the drug, the most probable antigen being bacterial protoplasm. This implied that bacterial death and lysis could be produced within an hour by a single massive dose of chloramphenicol. To investigate this point the following series of experiments was undertaken.

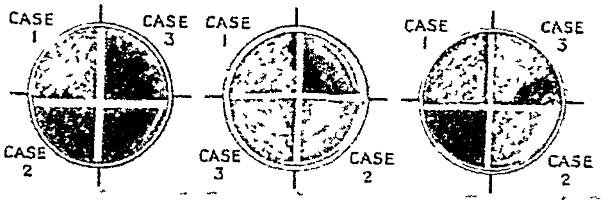

Fig. 9—Growths at twenty-four, forty-eight, and seventy-two hours in 3 of the 4 cases included in Fig. 8.

EXPERIMENTS ON ANTIBACTERIAL ACTION OF CHLORAMPHENICOL

Sterilisation of Upper Respiratory Tract

Four hospital patients, who were not suffering from whooping-cough (3 were convalescent from acute rheumatism and 1 had nephritis) and had not been given penicillin, sulphonamides, or streptomycin, were chosen. A postnasal swab from each was taken, as a control, and was plated on blood-agar. A dose of chloramphenicol at 100 mg. per kg. body-weight was then given to each patient and the postnasal space was swabbed at hourly intervals for six hours and at twenty-four, forty-eight, and seventy-two hours, the swabs being cultured on the same medium as the controls.

Fig. 8 shows the effect of chloramphenicol on the bacterial flora of the upper respiratory tract each hour for six hours; fig. 9 at twenty-four hours (case 4 was unexpectedly discharged and could not be followed properly), at forty-eight hours, and at seventy-two hours. The cultures show that massive bacterial death has taken place within an hour of

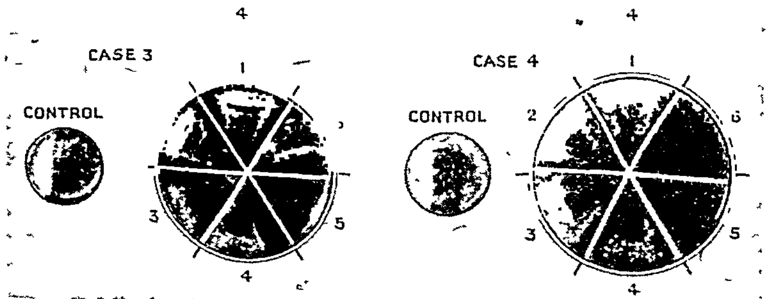

Fig. 8—Growths on blood-agar plates from postnasal swabs taken before chloramphenicol ("control") and hourly for six hours after single dose of 100 mg. per kg. body-weight. These patients were not suffering from whooping-cough.

a single dose, and that at least seventy-two hours is required for the flora to return to normal.

The organism in case 1, which seemed to revive at the fifth hour, disappear at the sixth, and reappear in pure culture at twenty-four hours, was a non-hæmolytic, coagulase-negative, *Staph. aureus*. At the fifth hour it was more gram-negative than gram-positive and the staining had to be controlled with a stock *Staph. aureus* to make sure that the appearance was not due to over-decolorisation. At twenty-four hours it was predominantly gram-positive. The chloramphenicol sensitivity of this staphylococcus was 10 µg. per ml., its penicillin sensitivity was about 0·1 unit per ml.

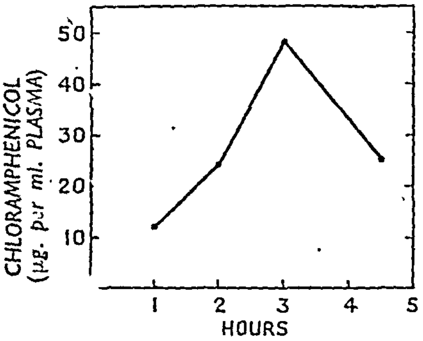

Fig. 10—Mean blood-levels of 4 cases included in fig. 8.

Fig. 10 shows the blood-chloramphenicol levels (average of the 4 cases) at hourly periods during the first four hours of the experiment.

Fig. 11 represents an extension of this work on the effect of chloramphenicol on the flora of the upper respiratory tract.

The patient (weight 10 kg.) was suffering from whooping-cough. A is a blood-agar plate culture of a postnasal swab taken on Sept. 15, before treatment. Between 4 P.M. on Sept. 16 and 8 P.M. on Sept. 17 he was given 1·5 g. of chloramphenicol by mouth, and treatment was then stopped. On Sept. 20 another postnasal swab was taken and plated; B shows the result.

The sterility of the upper respiratory tract appears to be maintained for a considerable time after the cessation of treatment in some cases. Fig. 12 illustrates this observation.

Two sisters, both with whooping-cough, participated in this experiment. One of them was given 5·875 g. of chloramphenicol in four days, while the other was given milk-sugar capsules of an equivalent dosage as a control. Five days after their last dose the postnasal space of each was swabbed and cultured. The growth on the left side of the plate is from the control; that on the right side of the plate is from the treated patient. It can be seen that the normal flora has not yet returned.

That complete sterility does not always occur is illustrated in fig. 13.

This patient was under treatment for a fractured humerus and had not been given any of the other antibiotics. His weight was 25 kg. He was given 2·5 g. of chloramphenicol as a loading dose, followed by a maintenance of 125 mg. three-hourly while awake. The course lasted four days. The cultures show the change in throat flora over a period of six days. All other organisms except a *Staph. aureus* were eliminated. This organism persisted in a diminishing concentration until treatment was stopped. Its chloramphenicol sensitivity was titrated at 12 µg. per ml. Its penicillin sensitivity was less than 0·1 unit per ml.

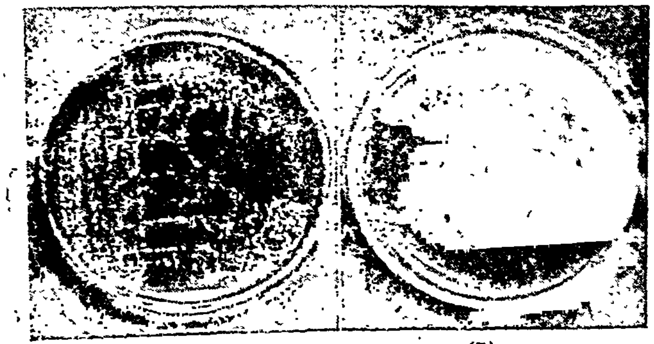

Fig. 11—Growths on blood-agar from postnasal swabs taken (A) before chloramphenicol, and (B) three days after course of 1·5 g. Patient with whooping-cough.

In following the course of this complete sterilisation of the upper respiratory tract, it has occasionally been found that a pure culture of *Strep. hæmolyticus* or *Staph. aureus* heralds the return of the organisms to the throat. These in turn have been outgrown by the α-hæmolytic streptococci and diphtheroids, the last to appear being *N. catarrhalis*.

Rectal Administration

By using serial postnasal cultures to estimate the efficacy of rectal chloramphenicol, the findings in the treatment of whooping-cough by this route have been confirmed.

A dose of 5 g. was given over a period of thirty-six hou to a child weighing 14 kg. Fifty-two hours after the en of this course, a swab grew 70 colonies of *Staph. aureus* an a scattered growth of *Strep. viridans* and *Strep. pneumonic* *N. catarrhalis* and the diphtheroids were absent. At hundred and ten hours, the *Staph. aureus* count had dropped t 21 colonies, but the α-hæmolytic streptococci had definitel increased. At a hundred and thirty-four hours there was profuse growth of all the ordinary comensals except *N. catarrhalis*.

Weakness of Accommodation

After a loading dose of 100 mg. per kg. body-weight, a transient ophthalmoplegia has been noted in children old enough to discuss their sensations. On reading, the print gradually blurs until the book has to be put down. After the eyes have been rested by using distant vision only, near vision becomes normal, but again after a few minutes' reading it reverts to the blurred state. This effect on near vision lasts about four hours. As far as can be ascertained, it coincides with chloramphenicol blood-levels of about 50 µg. per ml. and over. It has never been met while a patient is on maintenance dosage.

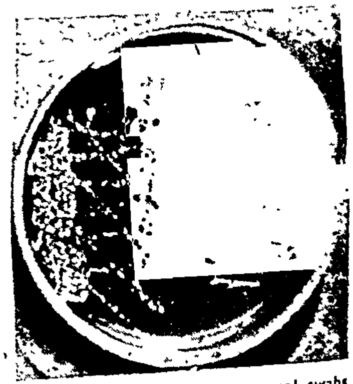

Fig. 12—Growths from postnasal swabs taken from two sisters five days after one (on left) had received a course of milk sugar, and the other (on right) a course of chloramphenicol.

Bilateral internal ophthalmoplegia is usually considered an indication of a central rather than a peripheral lesion. However, the waxing and waning of the condition with muscular use and rest suggested that it was peripheral, and that in some way the antibiotic was interfering with the metabolism of the ciliary muscle. It seemed essential therefore to find out whether this was a muscular metabolic change and whether the skeletal muscles were similarly affected. The following experiments were therefore undertaken.

Experiment 1.—A man, aged 50 years and weighing 80 kg., held a 14 lb. weight in the palm of his hand at arm's length and the period during which he could maintain this position—from the time of the outstretch until he dropped his arm—was timed with a stopwatch.

Before chloramphenicol the times were: 1st trial, 40 sec. (a rest for 5 minutes was then taken); 2nd trial, 37 sec. (rest as before); 3rd trial, 38·5 sec. Mean of trials, 38·5 sec.

A dose of 80 mg. of chloramphenicol per kg. body-weight was then given and three hours later, when the blood-

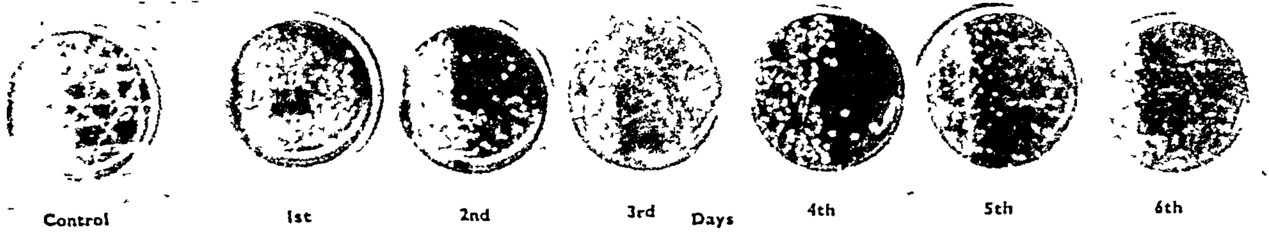

Fig. 13—Growths from throat swabs taken before chloramphenicol ("control") and then daily from start of four-day course.

loramphenicol level * was 48 µg. per ml., the test was peated.

After chloramphenicol the times were: 1st trial, 39·2 sec. est as before); 2nd trial, 23 sec. (rest as before); 3rd trial, 2·5 sec. Mean of trials, 28·2 sec.

The difference between the means is 10·3 sec.

Before chloramphenicol the man's near point for distinct inocular vision was 11$^3/_4$ in. and the diameter of his upils was 4·5 mm. While he was under the influence of hloramphenicol his near point was 13 in. and his pupil iameter 5·5 mm.

He described his subjective symptoms as: (1) dry mouth nd metallic taste; (2) extreme fatigue; (3) slight blurring f vision after reading for a few minutes; and (4) mental lepression.

Experiment 2.—The weight-holding test was repeated in a man aged 23 years and weighing 60 kg.

Before chloramphenicol the times were: 1st trial, 72 sec. (rest as in expt. 1); 2nd trial, 60 sec. (rest as before); 3rd trial, 58 sec. Mean of trials, 63 sec.

A dose of 100 mg. chloramphenicol per kg. body-weight was then given, and three and a half hours later, when the blood-chloramphenicol level * was 44 µg. per ml., the test was repeated.

After chloramphenicol the times were: 1st trial, 88 sec. (rest as before); 2nd trial, 34 sec. (rest as before); 3rd trial, 28 sec. Mean of trials 50 sec.

The difference between the means is 13 sec.

Before chloramphenicol the man's near point for distinct binocular vision was 3$^1/_2$ in., his pupil diameter was 5 5 mm., and Scheiner's test for his right eye was 7–8 in., and for his left eye 9$^1/_2$ in.

While he was under the influence of chloramphenicol his near point was 5$^1/_2$ in., his pupil diameter 5 5 mm., and Scheiner's test for his right eye was 9$^1/_2$–13 in., and for his left eye 10–12 in.

His subjective symptoms were: (1) dry mouth and metallic taste; (2) "fuzzy" close vision; and (3) a condition which he described as "postalcoholic convalescence."

Drug Resistance

As yet, acquired resistance by *H. pertussis* to chloramphenicol has not been encountered in this clinical trial. Attempts have been made in the laboratory to produce chloramphenicol-resistant strains of both *H. pertussis* and *H. parapertussis* by culturing on Bordet-Gengou media containing 0·1 µg. and 0·18 µg. of chloramphenicol per ml. After two twelve-day periods of exposure, titration of the organisms after final subculture showed that the original sensitivity had not altered. Further, *H. pertussis* does not seem to show the wide variation in strain sensitivity that is seen with the *Staph. aureus* group, the sensitivity of which may range from 2 to 12 µg. per ml.

It seemed advisable to make sure that the concentration of organisms in the inoculum played no part in the presumed strain variations in the staphylococcal group.

Two strains of *Staph. aureus* were chosen which had previously titrated at 8 and 12 µg. per ml. They were incubated overnight in peptone water, and then dilutions from these cultures were made in sterile normal saline to give concentrations of 1 millionth, 1/10 millionth, 1/20 millionth, 1/40 millionth, 1/80 millionth, 1/160 millionth, 1/320 millionth, and 1/640 millionth of the original. Viable plate-counts of the final dilution showed that the primary cultures contained respectively 2500 million and 1900 million organisms per ml.

One drop from a 50-dropper pipette from each of the dilutions was added to Khan tubes holding 2 ml. of glucose-phenol-red broth containing 6 µg. of chloramphenicol per ml. After four days' incubation the tubes were read. Fermentation had occurred in all tubes up to the 1/80 millionth dilution. After this point irregularity appeared, but consideration showed that successful inoculation of the broth from the final dilutions was a matter of chance.

It seems then that strain variations in sensitivity to chloramphenicol is a cell characteristic and is not dependent on the concentration of organisms present.

Action of Bacteria on Chloramphenicol

A final series of experiments were planned to inquire into the fate of chloramphenicol after interaction with bacteria.

The *Staph. aureus* with a sensitivity of 12 µg. per ml. was chosen for use. Nutrient broth containing 8 µg. of chloramphenicol per ml. was inoculated with this strain and incubated for five days, by which time growth was florid. The broth was divided into two parts after Seitz filtration. The chloramphenicol content in one part was estimated by chemical means. Serial determination showed that 8 µg. per ml. was present—the same amount that had been introduced into the broth originally.

This suggested that there had been no quantitative change in the chloramphenicol after reaction with the staphylococcus. (It should be mentioned that the chemical estimation does not distinguish between the active and inactive forms of the antibiotic.)

The remainder of the filtered broth was now used in the following manner:

Two rows of six Khan tubes (test and control), each holding 0·5 ml. of glucose-phenol-red broth, had been prepared. The test and control sets contained fresh chloramphenicol in concentrations of 0·4, 1·2, 2 0, 2·8, 3·6, and 4·4 µg. per ml., and to each of the test tubes a 0 5 ml. portion of the filtrate, equivalent to 4 µg. of chloramphenicol, was added. To each control tube was added 0 5 ml. of plain glucose-phenol-red broth. The tubes for the test now contained theoretical concentrations of 4·4, 5·2, 6·0, 6·8, 7·6, and 8·4 µg. of chloramphenicol, and those for the control 0·2, 0·6, 1·0, 1·4, 1·8 and 2·2 µg. per ml.

Both test and control tubes were inoculated with a standard loopful of a culture of *Sh. sonnei* with a known chloramphenicol sensitivity of 2 µg. per ml., and they were incubated for forty-eight hours. The end point was taken at the first tube showing no fermentation.

There was no difference between test and controls, the end point in both sets being 2·2 µg. per ml.

The same experimental method has been used in an attempt to isolate a chloramphenicolase (or chloromycetinase), but so far without success, though it seems that the reaction between organisms and chloramphenicol leads to inactivation of the antibiotic.

The conclusions to be drawn from these last two experiments might be summed up as follows. Chloramphenicol becomes inactivated when its antibiotic powers are exerted, and the process of inactivation does not involve the molecule as a whole but only part of it.

---

* The chloramphenicol levels in these two experiments are for whole blood estimated chemically and should not be confused with the preceding plasma-levels estimated bacteriologically. The two methods are not comparable.

DISCUSSION

It is not proposed to attempt an assessment of chloramphenicol in whooping-cough—for three very good reasons. First, the series is too small. Secondly, the objectivity of the observers is open to question. And thirdly, the widespread use of a pertussis vaccine may modify the disease in an incalculable manner. However, the trial has suggested that the correct dosage of chloramphenicol for any particular disease may be extremely critical, for in whooping-cough there is no apparent relationship between the in-vitro sensitivity of *H. pertussis* and the amount required to eradicate the same organisms in the body. This in turn may be related to observations made by Glazko et al. (1950)—that the highest concentrations of chloramphenicol are found in the kidney and liver, with progressively smaller amounts in the lungs, spleen, heart muscle, and brain.

Possibly more important than the effect of chloramphenicol on whooping-cough is the extraordinary indiscriminate bacterial holocaust it produces in the upper respiratory tract, the unusualness being enhanced by the speed with which it works and with the length of time that sterility is maintained. The future uses of this antibiotic in respiratory infections seem almost limitless, if the observations made on the upper respiratory tract can be extended to include the whole tract. This property will enable the chest surgeon to work in a field as sterile as any purist could desire, and this sterility can be maintained for as long as is required.

Attention must be drawn to the intense allergic reaction which occurred in one patient during these trials. It is important to bear in mind the possibility of precipitating unwelcome crises in those patients who have a direct bacterial background to their sensitive state, particularly if the doses of chloramphenicol given are large enough to cause the death en masse of their bacterial flora. Whether allergic patients of this type can be temporarily freed of their disability by the judicious use of chloramphenicol is open to trial. The question of massive bacterial death raises a further point for consideration: in the treatment of any condition with large doses of the antibiotic, the release of considerable amounts of protoplasm derived from the dead organisms may possibly produce a "toxic" state, so that the patient seems to be made worse instead of better.

Chloramphenicol has two disadvantages—its bitter taste and its relative insolubility—but its advantages over other antibiotics are enormous. It can be boiled without altering its potency; it is effective by mouth; accurate chemical estimation of its concentration is possible; a "chloramphenicolase" has yet to be demonstrated; and bacteria do not acquire resistance to the drug. Lastly, it is completely indiscriminate in the type of organism it kills. This indiscriminate action suggests that it may interfere with a metabolic system so fundamental that it is shared by most unicellular organisms. It was with this concept in mind that particular attention was given to the muscular changes induced by large doses of the drug. From the two cases investigated, it would appear that muscular fatigue does ensue, but there is no evidence to show how this is brought about.

Possibly the muscular changes are unrelated to the cause of bacterial death. However, bacterial and muscle metabolism have one factor more or less in common—their method of converting sugar to energy. Considering the problem from a unitarian standpoint, and invoking what help the muscle-fatigue experiments give, the crux does not seem to lie in the release of energy but in its restoration. The focal point of the latter is the pyruvic acid $\rightleftharpoons H_2$ coenzyme $\rightleftharpoons$ lactic acid relationship; and Smith and Worrel (1949), who have investigated the action of chloramphenicol on dehydrogenase from a bacteriological standpoint, can find no evidence of inactivation. The possibility of a "blocking" of lactic-acid combustion was therefore entertained and some preliminary experiments undertaken. However, until more information is available, further speculation is unwarranted.

Before large doses of chloramphenicol are advocated without reserve, two factors should perhaps be more closely studied. First, it is possible that the muscle-fatigue syndrome may extend to the myocardium. In the healthy young heart this may not matter, provided that undue exercise is not taken; but in the elderly, the toxic, and those suffering from heart-disease the interference with myocardial metabolism might be serious. Secondly, it is possible that the striking sterility induced in the upper respiratory tract by large doses of chloramphenicol may also occur in the gut. In infants this may seriously interfere with the synthesis of vitamin K, leading to a drop in hepatic prothrombin and the onset of a purpura.

A great deal more research is required before the place of this drug in the scale of antibiotics can be fully established.

SUMMARY

A clinical trial of chloramphenicol in whooping-cough has been made in two groups of children—(A) in the first two weeks of the disease, and (B) in the third or fourth week. In both groups alternate cases were given chloramphenicol or a placebo.

The cases were too few for definite conclusions to be drawn, but satisfactory oral dosage schedules were worked out. Owing to the persistent bitter taste of chloramphenicol, administration by mouth to children aged 1–3 years presents serious difficulty. Rectal administration was tried, with suppositories and with pierced gelatin capsules, but proved ineffective. Where chloramphenicol treatment is thought to be essential for children of this age, the drug may be given by stomach-tube.

One child developed an urticarial reaction after a single dose of chloramphenicol. Since she could not have had access to the drug before, it is supposed that her sensitivity was due to massive bacterial death.

Among the treated children given massive dosage, those who were old enough to notice visual symptoms developed a peculiar internal ophthalmoplegia characterised by rapid fatigue of accommodation on reading, with recovery after a short rest. This was thought to be a peripheral effect. Experiments in adults confirmed the existence of this side-action, and weight-holding tests showed that chloramphenicol hastens the onset of fatigue in skeletal muscles.

Serial postnasal swabs showed that chloramphenicol completely sterilises the mucous surfaces of the upper respiratory tract. The sterility lasts for 2–3 days after the last dose, but it can be maintained indefinitely by continuing administration. This property may prove of great value in surgery, especially if the sterilisation is found to extend into the lungs.

I am greatly indebted to Mr. J. A. Rouse, senior technician, Belgrave Hospital for Children, for his continuous help; to Mr. H. Daverson for the photographs; to Dr. B. W. Lacey for information regarding the cultural vagaries of *H. pertussis*; to Dr. J. Stanley White, of Messrs. Parke, Davis & Co., for access to unpublished information; to Dr. W. H. Bradley, of the Ministry of Health, for his support and interest; and to Mr. R. P. Crick for the ophthalmological examinations.

EFFECT OF DEOXYCORTONE AND ASCORBIC ACID ON FORMALDEHYDE-INDUCED ARTHRITIS IN NORMAL AND ADRENALECTOMISED RATS

GEORGE BROWNLEE
B.Sc. Glasg., Ph.D. Lond.
OF THE WELLCOME RESEARCH LABORATORIES, BECKENHAM

AFTER the observation of Lewin and Wassén (1949), hat a single intramuscular dose of 5 mg. of deoxycortone cetate, followed in a few minutes by 0·5–1·0 g. of ascorbic cid intravenously, produces symptomatic improvement n patients with chronic rheumatoid arthritis, it was of nterest to inquire whether similar effects might be bserved in animals, and particularly in adrenalectomised nimals.

EXPERIMENTAL TECHNIQUE

The animals used in these experiments were adult male albino rats of inbred Wistar stock maintained under uniform conditions of diet and management for many years. The experimental arthritis (Selye 1949) was produced by the injection of formaldehyde. Since much of the interest of these observations centres round those made in adrenalectomised animals a description of the methods which ensure the absence of endogenous adrenal hormones is desirable.

Male rats weighing 100–110 g. are anæsthetised with 0·08 ml./kg. of a 2·5% solution of bromethol in saline, injected ntraperitoneally. Anæsthesia is developed within 5 minutes and is sufficiently deep for surgical section in 10 minutes; recovery is incomplete for several hours and is smooth and free from excitement. The animals operated on, and indeed all the animals in these experiments, were housed at 24° ± 2°C. To offset overnight starvation a few drops of sugar solution were usually given.

The methods essential for complete adrenalectomy are discussed in detail by Schultzer (1935, 1936). Essentially, the kidney is exteriorised through an incision and the adrenal displayed. The pellicle of the gland is grasped with two finely pointed curved forceps without touching the gland itself, and is crushed and torn; the gland is then freed by a single upward pull. When now pulled caudally the adrenal gland, with about half of the attached kidney capsule, is freed in one movement. Any fragment of the upper part of the capsule is carefully removed. The right adrenal demands more care.

Of 684 male rats operated on in this way in these and other experiments 43 (6%) did not survive the operation, and 23 (3·5%) *did not die.* In all but 3 of the latter group remnants of cortical tissue were found at necropsy. Suspicious fragments were cut across and immersed in a dilute solution of silver nitrate. Sections which blackened within a minute were assumed to contain cortical tissue (Szent-Györgyi 1928). The mean survival time of the untreated adrenalectomised rats is 15·4 days ± S.D. 3·9 on a diet containing 7·9 mg./g. of sodium and 5·3 mg./g. of potassium.

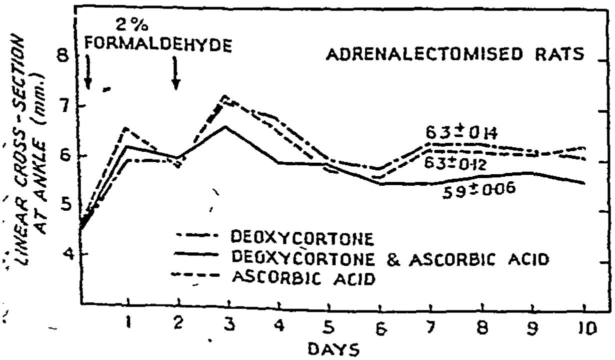

Fig. 1—Formalin-induced arthritis in adrenalectomised rats. Groups of 6 rats given deoxycortone 1 mg.; deoxycortone 1 mg. with ascorbic acid 20 mg.; and ascorbic acid 20 mg. Ordinates are measurements of the amount of the inflammatory process just below the ankle. The protection given by combined therapy is statistically greater than that given by the other two.

EXPERIMENTS WITH ADRENALECTOMISED RATS

Twenty male adrenalectomised rats were untreated for four days to promote exhaustion of the endogenous adrenal hormones. Additional sodium chloride, 1 part in 100, was added to their drinking-water to prolong their survival time. At this stage, all were injected in both hind feet, just beneath the plantar aponeurosis, with *0·1 ml. of 2% formaldehyde.* They were then divided into three groups each of 6 animals and treated differently. The first had 1 mg. of deoxycortone subcutaneously daily, the second 20 mg. of ascorbic acid intraperitoneally daily, and the third 1 mg. of deoxycortone subcutaneously daily with 20 mg. of ascorbic acid intraperitoneally at the same time. On the third day (the seventh after adrenalectomy) all the rats had a second injection of formaldehyde exactly as before.

The first effect of the formaldehyde is to produce an acute reaction which subsides in about two days; if formaldehyde is again injected there is a further acute reaction which subsides in two or three days. About five or six days after the first hyperæmic and œdematous response a chronic reaction begins, slower in onset and now distributed round the ankle-joint.

These effects are similar to those described by Selye (1949). Day-to-day changes in the inflammatory processes were recorded for each group by measuring the linear cross-section, immediately below the ankle, between the central aspect of the plantar aponeurosis and the extensor hallucis dorsis with a pair of engineer's screw callipers. The mean measurement, to the nearest half millimetre, of both feet in each group of 6 rats is shown for a period of ten days (fig. 1). The mean values for all the observations, with their standard errors derived from the group means, are also given. A simple analysis of the means and their respective standard errors makes it possible to estimate the significance. In the expression

$$t = \frac{M_1 - M_2}{\sqrt{s_1^2 + s_2^2}},$$

a comparison of the measurements in the rats receiving ascorbic acid with those in the rats receiving deoxycortone plus ascorbic acid yields a value of 2·6 for t. Entering the distribution of t at 19 degrees of freedom, 2·6 corresponds to the probability of this difference being obtained by chance once in fifty times. In the same way, the probability that the difference observed between the means for the deoxycortone group and for the deoxycortone plus ascorbic acid group is also real is expressed by a figure for t of 2·7, which corresponds to a probability of 1 in 75 that this difference might arise by chance.

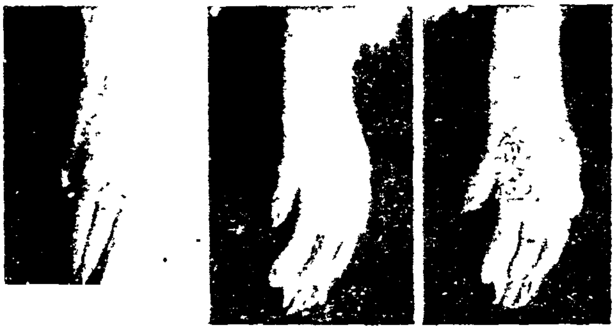

Fig. 2—Formalin-induced arthritis in adrenalectomised rats, on the tenth day (cf. fig. 1). *Reading left to right, deoxycortone 1 mg.* with ascorbic acid 20 mg.; deoxycortone 1 mg. alone; ascorbic acid 20 mg. alone. The group given combined therapy shows significantly less inflammatory change than the other two. (Here and in fig. 3 the means for each group, and their standard errors, are shown on the curves.)

Fig. 1 gives little indication of the observed degrees of difference seen between the groups, particularly, towards the end of the experiment. The differences are obvious to the eye and are reproduced in fig. 2.

EXPERIMENTS WITH NORMAL RATS

Three groups, each of 6 adult male rats, were treated with (*a*) ascorbic acid 20 mg., (*b*) deoxycortone 1 mg., and (*c*) deoxycortone 1 mg. plus ascorbic acid 20 mg. On the first and third day of therapy all the animals received an injection of 0·1 ml. of 2% formaldehyde just beneath the plantar aponeurosis of each hind foot. Measurements were made, as in the adrenalectomised group, and are reproduced in fig. 3, together with the group means and their standard errors.

A comparison between the means and their standard errors for the group treated with ascorbic acid and that given deoxycortone and ascorbic acid yields a t of 2. For 19 degrees of freedom this corresponds to a probability of 1 in 20 that the observation was due to chance. A similar comparison between the deoxycortone group and that treated with deoxycortone and ascorbic acid gives the figure of 4 for t, which corresponds to a probability of 1 in 1000 that the observed difference arose by chance.

The differences between these groups were obvious during the experiment, and in the case of groups (*b*) and (*c*) they were gross. They are illustrated in fig. 4.

DISCUSSION

The observation of Lewin and Wassén (1949), that a 5 mg. intramuscular dose of deoxycortone, followed by 0·5–1·0 g. of ascorbic acid intravenously, relieves the symptoms of chronic polyarthritis, is of great significance. The practical value of this treatment has been widely confirmed (e.g., Le Vay and Loxton 1949, Fox 1949), but in the fields of biochemistry and endocrinology the observation may have even more far-reaching effects.

The stimulus for this work derived from the demonstration by Hench et al. (1949) that 100 mg. doses of a chemically defined sterol, 'Cortisone,' produced dramatically beneficial effects in chronic rheumatoid arthritis. In this connexion it is of great importance that purified adrenocorticotropic hormone (A.C.T.H.) is also effective in rheumatoid arthritis (Hench et al. 1949). It is known that one effect of A.C.T.H. is to reduce the amount of ascorbic acid in the adrenal cortex, and indeed the method has been used for the quantitative estimation of A.C.T.H. (Sayers et al. 1948).

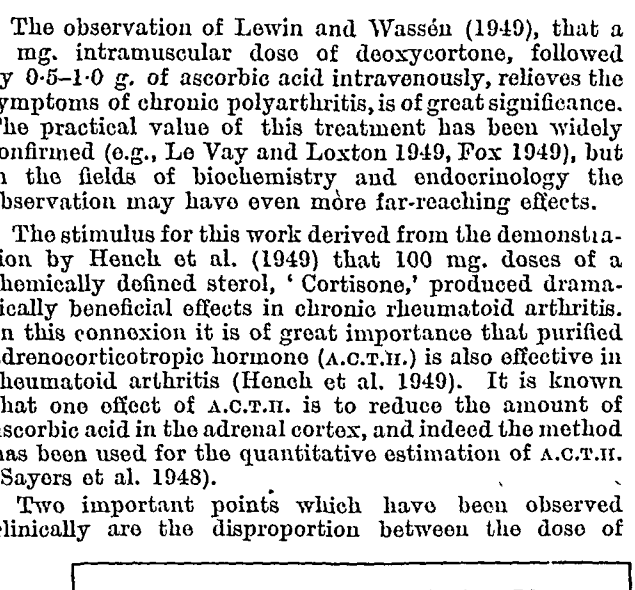

Fig. 3—Formalin-induced arthritis in normal rats. Groups of 6 rats given deoxycortone 1 mg.; deoxycortone 1 mg. with ascorbic acid 20 mg.; and ascorbic acid 20 mg. Most protection is given by combined therapy. Some protection is given by ascorbic acid alone. The inflammatory processes are aggravated by the injection of deoxycortone alone; this appears to be in contrast to the adrenalectomised group (fig. 1).

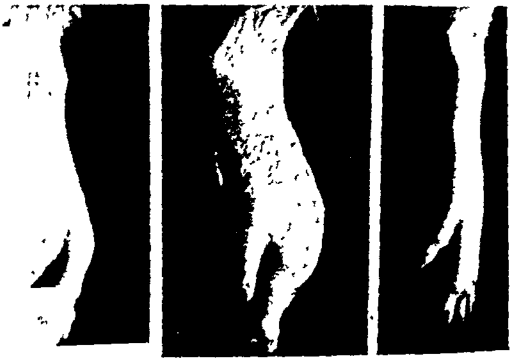

Fig. 4—Formalin-induced arthritis in normal rats, on the tenth day (cf. fig. 3). Reading left to right, deoxycortone 1 mg. with ascorbic acid 20 mg.; deoxycortone 1 mg. alone; and ascorbic acid 20 mg. alone. The group given combined therapy shows most protection, that given ascorbic acid alone some protection, while that given deoxycortone alone shows aggravation of the inflammatory process.

Two important points which have been observed clinically are the disproportion between the dose of deoxycortone (5 mg. or less) and the dose of cortisone (100 mg.) and the fact that the ascorbic acid must be given parenterally. The discrepancy between the dose of deoxycortone and of cortisone may also be true for the rat. Selye (1949) used 5 mg. of cortisone in adrenalectomised animals to obtain similar protection to that seen in the present experiments in adrenalectomised animals wit 1 mg. of deoxycortone plus ascorbic acid. It seem probable that a dose of 1 mg. of deoxycortone wit ascorbic acid is unnecessarily large, particularly in th normal animal, but in the adrenalectomised anim such a dose is essential for complete survival. Under ou experimental conditions we have established a quantitative titration curve for survival of adrenalectomise rats in the range of 0·25–2·5 mg. of deoxycortone p 100 g. rat. In this range doses of 2·0–2·5 mg. sho chronic toxic effects. A dose of 1 mg., on the other han gives almost complete protection against the effects o adrenalectomy for many weeks without toxic effects.

In the tests on adrenalectomised rats reported her the protection given against formaldehyde-induced arthritis in the group receiving deoxycortone combined with parenteral ascorbic acid is statistically significantly greater than that afforded by either ascorbic acid or deoxycortone alone. Moreover, the effect of combined therapy is similar in normal and in adrenalectomised animals. In the adrenalectomised group the effects seen in the deoxycortone group and in the ascorbic acid group are almost identical and do not differ statistically.

In normal rats the protective action of combined therapy is significantly greater than that of deoxycorto alone and probably greater than that of ascorbic ac alone. The considerable protection afforded by ascor acid is not unexpected and probably reflects the influe of ascorbic acid on endogenous adrenal hormones. Wh however, the normal rats treated with deoxycortone on one hand and with ascorbic acid on the other are co pared, the difference is highly significant, ascorbic showing a greater protective action. At 19 degrees freedom t=3, giving a probability of 200 to 1 agai the observation being due to chance.

Observations made during the administration o deoxycortone to formaldehyde-treated normal ra suggested that the sterol was exacerbating the inflamma tory process. The course of the curve in fig. 3 from th fifth day onwards suggests a similar conclusion. Th aggravating effect of deoxycortone is also described b Selye (1949) in normal animals. He als o seems to hav observed a slight aggravation of symp toms by deox cortone in adrenalectomised animals (see fig. 3 in Se 1949), but we have not observed this (compare fi and 3), and if it exists it appears to be mu ich milder th the aggravating effect in normal rats.

he points which have emerged from this work may tated as follows:

The therapeutic effect of cortisone on chronic rheumatoid arthritis in *man* (Hench et al. 1949) and its protective action against formaldehyde-induced arthritis in normal and adrenalectomised rats (Selye 1949) seem to have been reproduced by a combination of deoxycortone and ascorbic acid, both in man (Lewin and Wassén 1949) and in rats. Further, 5 mg. of deoxycortone with ascorbic acid appears to have approximately the same effect as 100 mg. of cortisone alone.

Ascorbic acid gives some protection against formaldehyde-induced arthritis in normal rats but not in adrenalectomised rats.

Deoxycortone alone aggravates the experimental arthritis in normal rats but not (or only very slightly) in adrenalectomised rats.

eoxycortone plus ascorbic acid, in the absence of ogenous adrenal hormones, seems to be an effective stitute for the naturally occurring anti-arthritic ol hormone. Since neither deoxycortone nor ascorbic l alone is effective in the adrenalectomised animal h substance must be essential to the biochemical nges involved. The possibilities are either that both xycortone and ascorbic acid, perhaps with other stances in addition, are components of an essential yme system, or that deoxycortone must first be nged chemically (reduced) by ascorbic acid before s effective.

he facts that ascorbic acid is present in the normal enal cortex but appears to be released therefrom by administration of A.C.T.H., and that it gives some tection against formaldehyde-induced arthritis when en parenterally to the normal animal, strongly suggest t ascorbic acid takes part in the biochemical reaction which the natural anti-arthritic sterol is involved.*

fact that ascorbic acid given by mouth, though l absorbed, is ineffective (Lewin and Wassén 1949) icates that the redox system may be implicated.

he aggravating effect of deoxycortone on inflammation an intriguing observation. Does this mean that ltered deoxycortone, though unsuitable as an antihritic sterol, may nevertheless compete with the ural sterol hormone as a building unit and thus cause npetitive inhibition, in the same way that sulphanilide is thought to compete with *p*-aminobenzoic acid ?

e apparent discrepancy between positive effects seen man with 5 mg. doses of deoxycortone combined th ascorbic acid, and the negative effects reported th 10 mg. doses of deoxycortone in combined therapy pies et al. 1949), may be explained by the aggravating ect of excess deoxycortone. It will be interesting to rn of the effect of combining ascorbic acid with tisone.

SUMMARY

aily parenteral doses of deoxycortone 1 mg., with orbic acid 20 mg., protect normal and adrenalectomised s against formaldehyde-induced arthritis.

n normal rats, but not in adrenalectomised rats, orbic acid 20 mg. parenterally offers some slight tection.

eoxycortone 1 mg. daily, parenterally, exacerbates formaldehyde-induced arthritis in normal rats, only to a very slight extent, or not at all, in enalectomised rats.

he significance of these experimental observations is cussed in the light of the current clinical developments.

REMOVAL OF FORCEPS FROM THE ABDOMINAL CAVITY

F. T. Ranson
M.B. Belf., F.R.C.S.E., F.A.C.S.

Margaret Blumenfeld
M.D. Leningrad

SHANGHAI

The leaving of hæmostatic forceps in the abdominal cavity at operation cannot be a very common accident, though undoubtedly more cases arise than are recorded. Most surgical textbooks ignore the subject, though Crossen and Crossen (1940, 1948) have written at length on it. Books on surgical errors, such as those of Thorek (1932) and of Burrows (1925), discuss the matter, and from time to time cases are recorded in the journals. Perhaps two of the best articles are those by Clifford White (1923) and by Greenhill (1933).

To the general public and to many doctors the accident seems inexcusable, but it has happened in even the best hands. The husband of the patient whose record is described here was horrified when he found what had happened to his wife, and remarked: "I have often heard stories about surgeons leaving things inside patients, but I always thought they were jokes."

CASE-RECORD

A married woman, aged 42, presented herself with a ready-made diagnosis of a hæmostatic forceps inside the abdomen.

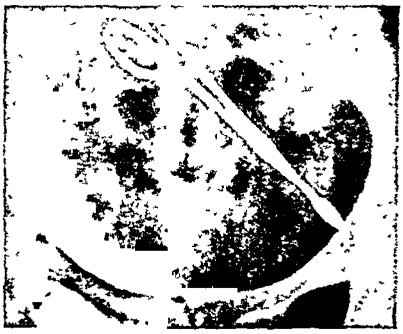

Fig. 1—Radiogram showing hæmostat in pelvis

Early in 1947 she had become pregnant, and in February of that year was operated on for a ruptured ectopic gestation. She recovered well from the operation and had no symptoms until October, 1948, when she began to have rather severe abdominal pain and from time to time noticed blood in the stools. She consulted different doctors without much benefit until one of them suggested an X-ray examination, which revealed a hæmostat in the pelvis (fig. 1). She was advised that the hæmostat should be removed.

Physical examination showed a healthy woman. There was a well-healed transverse scar in the lower abdomen. The hæmostat could not be felt by either abdominal or vaginal examination, though pressure in the lower abdomen evoked some pain. The blood-count, urine, and stool were normal; and chest-screening showed no abnormality in the lungs and heart. The history of blood in the stools suggested some erosion or penetration of the intestine, so a few days before operation on Dec. 13, the patient was admitted to hospital and given full doses of succinyl sulphathiazole.

Operation.—Under ether anæsthesia given through an Oxford vaporiser a median subumbilical incision was made. Numerous omental adhesions were separated, and it was found that the earlier operation had been on the right tube; the left tube was present but was distorted. The uterus was

dditional evidence pointing to the distribution of ascorbic acid in the tissues as an important factor in the causation of arthritis was provided by the convincing studies of Rinehart et al. (1938) in human *rheumatoid* arthritis. They found that the fasting blood-concentration of ascorbic acid was uniformly and severely reduced in patients with rheumatoid arthritis. Further, the administration of large doses of ascorbic acid produced, at best, a delayed increase in the plasma ascorbic-acid levels, and in some cases no response, even though the urinary excretion rate was high.

normal. To the right of the uterus and extending up into the right iliac fossa was a dense mass of adhesions among coils of small intestine, and through these adhesions could be felt the foreign body. It was deeply placed, and a tedious and blood-stained dissection was necessary before it could be seen.

It is difficult to describe exactly how this lay, but one handle was completely inside a loop of small intestine, while the other handle, part of which was missing owing to erosion, was buried in the mesentery. The shaft and tips of the forceps were partly in and partly outside the gut, the tips having traversed a loop of small gut and become adherent to the middle part of the left uterine tube.

To get the forceps out, the intestine was opened over the intact handle. A piece of tape was then passed through the handle and gentle traction applied to the tape. Cautiously the jagged ends of the other handle were extracted from the mesentery and drawn out through the hole in the intestine. The rest of the forceps (fig. 2) was then easily extracted. One large hole in the intestine, about 2 in. long, and two smaller holes were repaired. In repairing the large hole, it looked as though the intestine had been greatly narrowed. Resection of the affected loop was plainly desirable; but the loop could not be freed or brought into the wound without the probability of inflicting further damage, for the adhesions around it were very firm and dense. Some of the spectators suggested short-circuiting, but in view of the unavoidable contamination it was thought unwise to extend activities to other parts of the peritoneal cavity, and so short-circuiting was left for another operation, if required. A cigarette drain was inserted down to the right iliac fossa and brought through a stab wound, and the main incision closed. A transfusion of 500 ml. of blood was given.

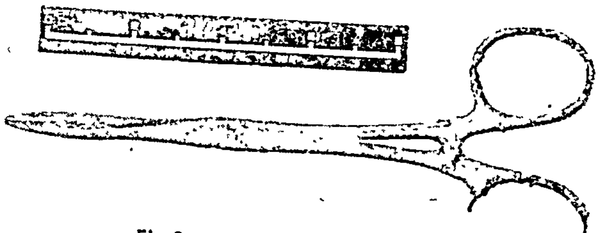

Fig. 2—Hæmostat after removal.

Progress.—For a few days we were anxious about the patient, but she did remarkably well. The drain was removed on the 4th day and the patient got out of bed. Though troubled with flatulence, she soon began to pass gas herself and within a week had a normal stool; and no fæcal fistula developed. Liberal use was made of streptomycin and penicillin in the postoperative period, and these medicines and the preoperative succinyl sulphathiazole may have been a factor in her speedy and smooth recovery.

When seen two months after the operation the patient was perfectly well, with no symptoms whatever.

DISCUSSION

The precautions taken in operating-theatres to prevent such accidents as that described here are not foolproof, and the responsibility for leaving something inside the abdomen rests with the surgeon. If after operation there is the slightest reason to think that an instrument may have been left in the abdomen, an X-ray examination should be taken; and the foreign body should be removed without delay. Clifford White records 13 instances where operation for removal of a foreign body was undertaken within a matter of hours or days, and all the patients recovered. When operation is delayed, however, the mortality is considerable, for two reasons: (1) owing to dense protective adhesions, the operation may be very difficult; and (2) the foreign body may have eroded or penetrated the intestine.

X-RAY CINEMATOGRAPH IN CONGENITAL HEART-DISI

Prof. ROBERT JANKER
M.D.

FROM THE RÖNTGEN- UND LICHTINSTITUT JANK

ANGIOCARDIOGRAPHY by rapid serial radio being increasingly used as cardiac surgery dev this technique is often sufficient for diagnostic but it cannot give a continuous picture of the the heart and is likely to miss some of the i details of this process.

As early as 1931, when there was still no indic human angiocardiography, X-ray cinematograp the injection of radio-opaque substances was be at Bonn to demonstrate the atria, ventricl great vessels in animals. More recently this metl been adopted in the diagnosis of human heart and we have abandoned serial radiography.[1]

METHOD

Before the radio-opaque substance is injecte patient is submitted to a careful clinical exam and is tested for iodine idiosyncrasy. The ne surgical interference must also be established. P exposure of the skin to X rays should, as far as p be avoided. For the X-ray cinematography its patient should have an empty stomach and sho placed lying on his back. Usually an anæsthe unnecessary, but if the patient is restless, hy hydrobromide can be given subcutaneously.

The radio-opaque substances used are 70% 'Iod (Cilag) and 80% 'Per-Abrodil M' (Bayer). Durin taking of the film 30–60 ml. (according to the pati size and age) of one of these substances is inj through a special wide cannula into the exposed m cubital vein, the injection taking 1–2 seconds. effects, such as cardiac arrest lasting a few sec coughing, vomiting, headache, a slight fall in bl pressure, and moderate cyanosis, are generally qui abolished by giving oxygen.

APPARATUS

The X-ray cinematograph had to be adapted angiocardiography. The shock-proof X-ray tube (RÖ Oil-Rotalix, made by Messrs. C. H. F. Müller), wh has a high capacity and a focus of 1·2 mm., is arran above the lead-protected table which contains fluorescent screen, with its fluorescent side downwar The image of the fluorescent screen, against wh lies a fine-line grid, is reflected to the cine-camera a silver-surfaced mirror. The camera is fitted with lens with an aperture of 1 : 0·85 (Leitz or Zeiss). T camera was constructed for me (Askania-R.-Kame Janker) in such a way that the open sector of the rota shutter is enlarged at the expense of the obscuri sector, and the film is exposed through 270° out of ea revolution of the shutter. The highly sensitive 35 m 'Fluorapid-Film' (Agfa) is used.

The camera is mounted on a rail so that it can be moved forwards or backwards, and with appropriate adjustment of the lens the screen can be recorded in various sizes—e.g., 35 × 35, 30 × 30, or 24 × 24 cm.

Before and during the taking of the film the screen can be watched from the control room through a hooded slit-like window of lead glass. By a similar arrangement it is possible to make observations of the cardiac catheter for diagnostic purposes—e.g., for taking samples of blood from the various cavities of the heart for measurement of oxygen saturation.

---

[1] Janker, R. Die Röntgenkinematographie. Stuttgart and Berl Kohlhammer 1939.

The X-ray apparatus now in use is the condenser del made by Messrs. C. H. F. Müller, with a capacity to 90 kV of direct current. The data are 90 kV and mA at a focus-film distance of 65 cm. Since the whole ocess does not last longer than 6–8 seconds, there are objections to the use of X rays of such intensity. The in is exposed to a dose of about 50 r. By means of a rther attachment (constructed by Mr. Kleimann of essrs. Müller's staff) the tube is only in action while e rotary shutter is open, and in this way the X-ray osage reaching the skin is reduced by a further 25%.

The number of frames which can be exposed per cond depends on the patient's size and build, stout atients requiring a longer exposure than thin ones. sually 18 but occasionally 24 frames a second are xposed. It is hoped to increase this number by raising ne voltage. At present much the same effect is achieved y incorporating a specially constructed copying apparaus, by means of which each frame exposed is copied up to wenty times ; thus the whole process is "stretched out" n projection, which is a great help in diagnosis.

Further improvements may be expected from the introluction of stereoscopic films, which are now still in the xperimental stage.[2]

APPLICATIONS AND RESULTS

Up to now we have used this method in the investigaion of congenital cardiac defects, to decide on the dvisability of surgery in such conditions as Fallot's etralogy, Eisenmenger's syndrome, truncus arteriosus ommunis, pulmonary stenosis, tricuspid atresia, &c. It has enabled us to confirm the diagnosis and the need for operation—in some difficult cases diagnosis has only been possible by this means—and it has enabled the urgeon to map out his landmarks, to decide on which ide he should operate, and to choose the vessels to be used for anastomoses.

Apart from its importance in diagnosis, this method, unlike all others used in examining the heart, enables us to study the minute details of the blood-flow through the heart and great vessels, thus providing important physiological information regarding the function of the deformed heart.

The accompanying figure is an enlarged still from an angiocardiographic film of a girl, aged 9 years, who had Fallot's tetralogy, with congenital cyanosis, clubbing of the fingers, and considerably reduced functional efficiency. The deficit of arterial oxygenation was 30%. Angiocardiography reveals that the aorta and the pulmonary artery fill practically at the same time. The pulmonary stenosis can be seen proximal to the valve. The pulmonary artery is dilated beyond the stenosis. The right ventricle is enlarged to the left. On the left side a vessel suitable for anastomosis can be seen.

Enlarged still from an X-ray cineradiographic record of a case of Fallot's tetralogy.

In this case angiocardiography confirmed the diagnosis and the indication for operation and showed Prof. Derra, the surgeon, on which side to operate, thus playing an important part in the success of the operation.

Details of the apparatus will be published in *Fortschritte auf dem Gebiet der Röntgenstrahlen*. The technique has been developed in collaboration with Prof. Grosse-Brockhoff and Dr. Schaede, of the Medical Clinic of the University of Bonn, and Prof. Derra, director, Surgical Clinic, Medical School of Düsseldorf.

Preliminary Communications

HÆMOPHILUS INFLUENZÆ MENINGITIS

A POSSIBLE ECOLOGICAL FACTOR

In the course of a larger study of a series of cases of *Hæmophilus influenzæ* meningitis, an attempt was made to find common factors bearing on the epidemiology and ætiology of the disease.

Findings

Negative.—(1) No patient had contact at any time with any other patient, nor had the families of the patients any acquaintance or contact with one another. (2) In no case had any member of a patient's household any known illness during the three weeks preceding the onset of that patient's disease. (3) No clinical evidence was found of a potentiating viral infection preceding the infection by *H. influenzæ*. (4) The children were not drawn from any particular area, income group, race, or religion.

Positive.—(1) The patients themselves were healthy children of normal development before the onset of the disease. (2) The age-distribution was from 3 months to $3^{1}/_{2}$ years : this is the usual age-distribution of the disease (Smythe 1948, Dubos 1948). (3) The families of the children were strikingly large, and every patient had two or more elder living siblings aged less than 12 years.

Facts from the Literature

Dubos (1948) discussed the variation of the quantitative bactericidal power of the blood of healthy Americans against the smooth meningeal strain of the Pitman type B organism, at different ages. The titre was high in infancy and fell abruptly to zero at 3 months. From 3 months the level remained low until 3 years, when a steady rise began. The curve flattened at the age of 8 and from the age of 10 was sustained at a maximum into adult life. Children who developed meningitis were drawn almost exclusively from the age-group with the lowest bactericidal power. Children aged 3–12 have submaximal bactericidal titres.

Good et al. (1943) found a high carrier-rate among the siblings of children with hæmophilus meningitis.

The hospital incidence of the disease has risen recently in Norway (Grelland 1946), in Denmark (Engbaek 1948), and in England (Braid and Meyer 1949, Ounsted 1949). The English birth-rate has shown an increase in the same period.

The disease is never reported as occurring in epidemic form.

Statistical Examination of the Present Series

Problems.—It is necessary to show that the number of elder siblings aged less than 12 years in the hæmophilus group differed significantly from that of the general hospital population of the same mean age. Further it has to be shown that hæmophilus infection differed in this way from other infections, and in particular from other meningeal infections, in children of the same age-distribution.

Methods.—Two control series were evolved. One consisted of a hundred consecutive admissions to the children's wards of the Radcliffe Infirmary aged 3 months to 4 years, and the other of fifty-two consecutive cases of meningococcal meningitis of similar age-distribution and admitted to the same ward. The control groups were then set against the hæmophilus group and against one another, and statistical tests were applied to the absolute figures.

Results.—Detailed examination of the control groups suggested that they were biologically valid controls.

It is clear from the percentile figures (see figure) (*a*) that the meningococcal group and the over-all hospital population follow an almost identical pattern, and (*b*) that the hæmophilus group follows an entirely distinct pattern.

Since the numbers in the hæmophilus group were small it was necessary to test the absolute figures. For example:

Group	No. with two or more elder sibs	No. with less than two elder sibs
(*a*) 100 controls ..	26	74
(*b*) 13 *H. influenzæ* cases	13	0

When the χ-square test is applied to these figures a value of $\chi_1^2 > 22$ is obtained—a "highly significant" result.

The absolute figures of the meningococcal and control groups have been compared over the first four sibling groups:

No. of siblings	0	1	2	3 and over
52 meningococcal cases ..	27	13	8	4
100 control cases.. ..	47	27	16	10

Application of the χ-square test gives a value of $\chi_3^2 = 0{\cdot}429$, showing that the close parallelism of the percentile figures (see figure) is statistically valid.

Conclusions

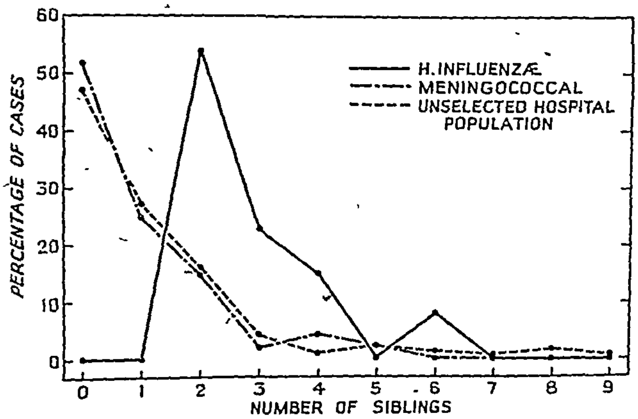
Children admitted to hospital with meningitis due to *H. influenzæ* have contact with two or more elder siblings aged less than 12 years.

Children with meningococcal meningitis have a sibling pattern identical with that of the general hospital population of the same mean age.

The distinctive pattern in the hæmophilus group is not, therefore, due to any peculiar liability in the younger children of large families to meningeal infection per se.

Ad-hoc Hypothesis

On the tenuous basis of these facts a hypothesis was formed. It seems possible that the *H. influenzæ* organism requires one or two bacterial passages thro partially immune contacts, before a strain is evol that can pass the meningeal barrier. The problem under further study.



I wish to thank Dr. V. Smallpeice for encouragement permission to publish.

ARTERIOVENOUS ANASTOMOSES IN THE STOMACH WALL

ANATOMICAL evidence for the presence of arterioven anastomoses in the wall of the human stomach is n accumulating. De Busscher[1] described complex arte venous anastomoses of the glomus type, and Barlo has demonstrated by microdissection the presence simple direct arteriovenous channels in the submuc connective-tissue of the stomach. That such anastom may be present was deduced by Barclay and Bentl from their investigation of the gastric blood-vessels means of micro-arteriography.

In view of this evidence an attempt was made demonstrate physiologically the existence of arte venous shunts as *functioning* entities. Human stoma removed at operation have been perfused at a tempe ture of 37°C in a moist atmosphere, within a few minu of operation. They remain viable for many hours tested by the response of the vessels to drugs. Perfus at a pressure of 120 mm. Hg, is made by means o cannula in the right gastro-epiploic artery, the o flow being collected from a cannula in the right gas epiploic vein; the cut ends of all other vessels are clam or tied.

When microscopic glass spheres of known diame are introduced into the perfusate entering the arte cannula, the outflow from the gastro-epiploic vein found to contain these spheres in considerable numbe The mean diameter of the spheres injected is 16 (S.D. 52) and the mean size of the spheres found in outflow is not appreciably different. It can be conclu therefore that arteriovenous anastomoses exist in stomach wall capable of passing glass spheres of at le 160 µ diameter.

"... There is no one good word to describe what medi ought now to become. Those who believe doctors should wiser than they are now deny the exclusive claim of older medicine to the name *scientific*: they believe medic should become more scientific, in the sense of admitting d now commonly left out of consideration. Medical progress use the word *preventive* when they think of what medi could do before pathology develops; *constructive* when t set 'positive health' as their goal; *comprehensive* when t ask doctors to deal with people whole instead of in pa *social* when they feel the pressure of the human environm on the individual and want the doctor to be at least aw of it. All these concepts are facets of good medicine. *Annual report of the Commonwealth Fund*, 1949.

Medical Societies

BRITISH TUBERCULOSIS ASSOCIATION

Debate on Infection

THE British Tuberculosis Association met on Jan. 20, der the chairmanship of Prof. F. R. G. HEAF, the esident, to debate the proposition That Infection, hough Necessary, is Not the Major Factor in the revalence of Tuberculosis. In the end no vote was ken.

Dr. H. J. USTVEDT (Denmark) said that whilst no-one ould deny that without tubercle bacilli there would be o tuberculosis, this was a dangerous slogan, since it oncentrated attention too much upon the infecting rganism and left the "constitutional factors" out of the icture.

What evidence there was did not support the ssumption that differences in the virulence of the organism greatly influenced the prognosis of primary tuberculosis. It was strange how deeply rooted was the concept of "massive infection." Belief in the decisive importance of the infecting dose seemed to derive mainly from misinterpretation of experiments on animals, where the bacilli were injected, and of the striking frequency of tuberculous disease in contacts. Even Rich, however, admitted that the number of air-borne bacilli which could lodge at any one site in the lung could hardly be regarded as massive. In Dr. Ustvedt's opinion, the importance of the infecting dose under natural conditions was minimal.

Superinfection—a new infection where the primary was still living, though possibly latent—might take place in the pre-allergic phase after primary infection, in the allergic phase, or in the postallergic phase, where the sensitivity to tuberculin had waned but some form of allergy remained. There was indirect evidence that superinfection could hardly be of major importance. There was also little reason to doubt that tubercle bacilli inhaled into the alveoli of people already infected with tuberculosis, and allergic, might invade the lung tissue; and it seemed highly probable that superinfection might stimulate the tuberculin sensitivity of the skin.

As to whether superinfection influenced the course of tuberculosis the pathological evidence was inconclusive. The frequency of the disease in contacts could not be used as an argument for the importance of superinfection, for a series of factors were involved. In this regard the large amount of material regarding marital tuberculosis was also valueless. Dr. Ustvedt agreed with A. L. Jacobs's comment on the Prophit survey that the important social and environmental disadvantages in group A (nurses) were quite adequate to explain the relatively small excess morbidity. Whilst superinfection might occasionally produce tuberculosis in B.C.G.-vaccinated individuals who were still regarded as tuberculin-positive, it must be remembered that generally the course of the disease in vaccinated subjects seemed to be rather benign. However, under ordinary conditions tuberculous disease in tuberculin-positive individuals, occurring after the period of primary infection, must be assumed to depend either on exacerbation of old foci or on dissemination.

Dr. Ustvedt then turned to the question of the higher tuberculosis morbidity among medical-student invertors than among other student invertors. As to whether this difference was real or was due to factors inherent in material or methods, the technique of testing might be important. In the international tuberculosis campaign the final dose for the Mantoux test had been lowered from 100 toxic units (T.U.)—corresponding to 1 mg. of old tuberculin (O.T.)—to 10 T.U., because of frequent reactions to Mantoux 100 T.U. which were assumed to be non-specific. The question whether medical students, who were exposed to much more tuberculous infection than their comrades in other faculties, really showed a higher morbidity could not be regarded as settled.

Summing up, Dr. Ustvedt said that there was little support for the assumption that infection in itself was of major importance in tuberculosis, apart from being a necessary condition. Possibly under special circumstances the infecting dose or the virulence of the organism, or superinfection, might have a rôle, but statistically this had not been proved. The tuberculosis destiny of an individual must be determined predominantly by hereditary factors, age of infection, and non-specific resistance, depending upon nutrition and other environmental factors and immunity.

Dr. L. E. HOUGHTON did not doubt that differences in racial constitution caused well-marked variations in the reaction to the tubercle bacillus. The Prophit survey drew attention to variations in opportunity for infection in certain groups of nurses, but no such observation could explain the increased incidence among the Irish and Welsh nurses. There existed also hereditary transmissible differences in the degree of native resistance.

Apart from infancy, the age of greatest hazard for females was 15–30 years. In Britain the male peak seemed to be steadily shifting to the right and was now between 40 and 50 years, the over-all incidence being greater than among females. The differences in morbidity and mortality rates among children of different ages were also interesting. It would be hard to explain these phenomena almost entirely by opportunity for infection.

Undernourishment was recognised as a factor which promoted abnormal sensitivity to the bacillus, though which food factor might be responsible for the fluctuation in resistance was not established. Physical overstrain did not appear to be a factor in the ætiology, though it affected active lesions. In some cases anxiety might be one of the most potent precipitating factors of tuberculosis; and if there was any truth in the historical association of genius with tuberculosis, this was probably the explanation.

The dramatic effect of streptomycin and other antibiotics and drugs seemed to emphasise the overriding importance of the infection factor. But, of course, "without tubercle bacilli, no tuberculosis." Furthermore, streptomycin might well have profound effects other than the elimination of tubercle bacilli. It was certainly true that resolution of tuberculous lesions sometimes continued long after streptomycin injections ceased, and that clinical improvement might continue even though complete streptomycin resistance had been established. It was the behaviour of the tissues in contact with the tubercle bacilli which determined the fate of the patient.

Dr. PETER EDWARDS, opening for the opposition, said that a happier and more cheerful crowd than his patients it would be difficult to find. He believed that Dr. Houghton had mixed up a cause of tuberculosis and the attitude of patients who had got the disease. The Prophit survey showed a greater incidence of tuberculosis among nurses in hospitals with tuberculosis wards; and it was known that sanatorium nurses had a low incidence where there was proper education and technique.

On contact infection, Dr. Edwards pointed out that the small number of tuberculous people produced one-third of the total incidence in the whole population. He thought that it could be concluded that infection and the repeated dose were important. At Liverpool in 1860, when 13·7% of deaths from tuberculosis took place in hospital, the mortality in the population was 44 per 1000. In 1946, when deaths in hospital were 57%, the mortality was 0·9 per 1000. This indicated that mortality dropped with segregation. The same had been found in the U.S.A. In a sanatorium a man with human tuberculosis who had shared a cubicle with a man suffering from bovine tuberculosis who was of the “ uneducatable ” type, left the sanatorium with the human disease plus the bovine ; and Dr. Edwards could only think that this was due to infection. Infection seemed the chief factor and all preventive methods ought to be directed against it. He believed that education in hygiene was most important ; and cases should be found, isolated, and treated.

Dr. **Alice Stewart**, the second speaker against the motion, referred to her investigations in the boot-and-shoe industry, where the incidence of tuberculosis was found to be two or three times higher in the larger factories than in the smaller ; they were driven to the conclusion that a proportion of cases had arisen at work, by infection. Another investigation had shown that the incidence of tuberculous cases in houses next door to houses with a case of tuberculosis was 16% in excess of what would normally be expected.

Investigation in a workroom where four young women were discovered, by mass radiography, to be suffering from pulmonary tuberculosis, revealed that there had been previous cases, and ultimately that a man working in the room had been shown post mortem to have been suffering from tuberculosis. His wife died of tuberculosis in 1924, but he was not examined at that time. In 1942 his daughter died of the disease, but again it was not detected in him. There was very suggestive evidence that this man was responsible for causing the disease in people who might otherwise never have had it. From long-term studies of groups sufficiently well defined there was also evidence that grouping people together at work was liable to increase the incidence. After describing in detail the variations in the tuberculosis death-rate from 1881 to 1931 in three trades, which all had a strong family tradition—the printing trade, the shoe-making trade, and fishing—Dr. Stewart concluded that with any infectious disease the larger the exposed population became, the more resistant would people become. This would explain many so-called genetic factors. “ Highly resistant as we are, it is still not safe to leave people to be exposed to this infection.”

Dr. **G. Canetti**, of the Pasteur Institute, Paris, maintained that superinfection was of primary importance in the pathogenesis of tuberculosis. Foci of superinfection were not rare ; they appeared usually in the upper part of the lung and were small, though they passed through the same changes as primary foci. They were met with more frequently in older subjects, and were seen long after the primary foci had been cured. If tuberculosis arose five or six years after the primary infection, he believed that it was due to superinfection.

Dr. **A. L. Jacobs** answered the question : “Why are a large number of people infected with tuberculosis but only a small number develop the disease ? ” by saying that such factors as age and environment were more important than the static factor—the infection. The fact that superinfection foci existed was no more significant than the fact that primary foci existed ; the constant factor was the same in both.

Over-all figures from an Italian survey of 59,000 people working in hospitals for the tuberculous showed that the average morbidity amongst administrative and office workers was 4·9 per 1000, among medical and nursing staff 8·7 per 1000, and among nuns working in institutions 18 per 1000. Why should the incidence among nuns carrying out nursing duties be so m higher ? Surely the considerable differences in th of life of the nuns from that of the other nurs something to do with it ?

Dr. **Halliday Sutherland** said that he had livened up a meeting by declaring : “ When discovered the tubercle bacillus, he put the clock b And there was a great deal of truth in it. Before doctors had been asking themselves : “ What is change which occurs in the humors of the body enables tubercles to grow ? ”—which was the que they were asking today. The incidence of tubercu fell most steeply between 1860 and 1882, because that period there was a great improvement in so conditions, which improved the resistance of people.

Dr. **Clark Penman** thought that Dr. Sutherla was very keen on putting the clock back. *But by lea* ing the clock where it was they had a form of atta which had been very successful in Minnesota a Saskatchewan.

Dr. **J. S. Westwater** had not expected the motic to be taken so seriously. When he had heard D Houghton suggest that anxiety was an important facto he wondered whether the increase in the disease Scotland during and since the war was because t people there were more anxious than in England. The when he heard Dr. Houghton associate genius wit tuberculosis, he thought he had the answer.

Dr. **Marc Daniels** remarked that there were tw major factors—infection and resistance. The motio presupposed there was *only one*, so he urged member to abstain from voting.

Dealing with superinfection, Dr. Daniels recalled that the Prophit survey had shown a primary-infection rate of 26% in the controls, 54% in group B nurses, and 80% in group A nurses (those in hospitals with many tuberculous patients). The degree of tuberculin sensitivity in tuberculin-positive nurses rose rapidly in the first year of nursing, and more so in group A than in group B. This was interpreted in the survey as evidence that superinfection took place. The survey further found that the annual morbidity-rate per 1000 was 7·0 in group B nurses and 11·3 in group A—that is, it was 63% more in A than B—and group A were more frequently infected than group B. Dr. Jacobs had stated that the difference between A and B was very small, being only 0·4%, by which root of calculation the rise in tuberculosis mortality in Warsaw during the war from 150 per 100,000 to 500 per 100,000 was a paltry affair—a mere 0·35%.

Differences in resistance might be responsible some of the difference in morbidity, but the rest w probably due to increased infection. If there was large a difference in constitutional resistance as Jaco suggested, one would expect the disease to be mo severe in group A than in group B ; in fact there was difference in severity.

Most believed that the bacilli responsible for tube culosis in adults might come from a recent primar focus, from exacerbation of an old focus, or from a added infection from outside. What proportion o cases were due to one or the other, was not known. They should let it rest there in a spirit of healthy agnosticism until further evidence was forthcoming.

Dr. **Reti** (Israel) pointed out that very little had been said about the bacillus itself, and its host, from the biochemical angle. It had been found that a complicated enzyme system was necessary to build up the tubercle lipoids, and one must bear in mind the functioning of this enzyme system and the counter-action of the host to neutralise it.

LIVERPOOL MEDICAL INSTITUTION

Ulcerative Colitis

At a meeting on Jan. 5, with Prof. Charles Wells, the esident, in the chair, ulcerative colitis was discussed.

Dr. S. W. Patterson said that after excluding the ll-defined causes of ulcerative colitis, such as amœbic d bacillary dysentery (which occurred not only in opical climates but also in this country, especially in fants and elderly patients in institutions), tuberculous ceration of the bowel, and syphilitic proctitis, there mained a characteristic syndrome which formed a sease-entity. The cause of this was still unknown. ypically the course was relapsing, with gradually creasing diarrhœa, the motions containing blood and ucus. This group of patients often responded to rest nd simple dietetic measures and commonly the disease as self-limiting. In the treatment diet was important, he object being to support the patient and yet not rritate the bowel; sufficient vitamins should be supplied, nd for the diarrhœa antispasmodics and sedatives; bsorbents, such as kaolin and bismuth, and rarely opium might be given. The sulpha drugs were best dministered in retention enemas—gr. 45 in 6 oz. of water—two or three times in the twenty-four hours. Anæmia and dehydration should be countered by blood-transfusion, supplemented with iron by mouth and liver extract by injection. Lavage of the colon with antiseptics and douches had been largely abandoned. These patients often showed immature personality, childishness, fussiness, and anxiety; and mild encouraging psychotherapy was needed.

Two types of greater severity were common: (1) the fulminating, especially in young patients with poor resistance; and (2) the chronic, which resisted treatment and had long severe recurrences characterised by wasting, fever, dehydration, anæmia, and tachycardia, with extension of ulceration from the sigmoid to the whole colon and often to the terminal ileum. Inflammation round the rectum, with abscess and fissure, and skin lesions ranging from acne to gangrenous dermatitis were common. In these severe cases ileostomy was the operation of choice; and after improvement, through resting the colon, colectomy was indicated. The object must be to control the symptoms, to arrest the inflammatory lesion, and to prevent invalidism. Even after three or four years of desperate illness, patients recovered and the remission might be permanent.

Mr. R. B. Welbourn said that there was no known cure for ulcerative colitis, but that surgery could save life, increase the expectation of life, and make life more tolerable. The aim of treatment was physiological rest for the colon, and this could be achieved by terminal ileostomy. When performed on patients in extremis, this carried an operative mortality of at least 50%; but many of those who survived were restored to health. Ileostomy should be adopted as an elective procedure in any patient who did not respond to a fair trial of medical treatment; and the operative mortality was then less than 10%. It had been shown statistically that this procedure gave much better immediate and long-term results than medical treatment. The testimony of patients who had an ileostomy was that it was much preferable to the distressing symptoms of ulcerative colitis. A "spout" type of ileostomy, covered with skin, was preferable to the usual "flush" type, because it delivered the fæces directly into a bag and prevented soiling and excoriation of the abdominal wall; and patients found it more manageable. If the disease remained active, colectomy might be necessary; and this was becoming commoner as a routine procedure to prevent complications such as severe hæmorrhage or malignancy, which might still arise after ileostomy. The operative mortality was low. Most patients who had an ileostomy were destined to keep it for life, because attempts at restoring a functioning anus usually resulted in a relapse, even after subtotal colectomy and ileorectal anastomosis. It was too early to say whether total colectomy and excision of the rectum, followed by an ileal "pull-through," would give any better results.

Dr. A. R. D. Adams remarked that bacillary dysenteric and amœbic dysenteric infections, though particularly prevalent in the tropics, were also common in Britain. Amœbic dysenteric infection contracted in the tropics commonly caused acute dysentery; when it was contracted in temperate climates acute symptoms were comparatively rare. But the incidence of acute cases even in the indigenous population was greater than was generally supposed, for when these cases did arise the diagnosis was missed and they were treated as chronic ulcerative colitis; one patient at present in hospital had been dealt with in this way for twenty-six years. The importance of examining the stools microscopically in all cases of chronic colitis could not be overemphasised, and amœbic dysenteric infection should always be excluded by this means before idiopathic ulcerative colitis was diagnosed. The treatment of acute amœbic dysentery by emetine injections was well known, but it was less well known that to sterilise the infection a variety of drugs must be administered in concert for some weeks.

As a sequel to severe dysentery, chronic ulceration of the bowel, due to recurring breakdown of scar tissue, was not uncommon. This persisted after the primary infection had disappeared, and differed little from idiopathic ulcerative colitis. Owing to better diagnosis and specific treatment of acute dysentery, post-dysenteric colitis was much less prevalent after the second than after the first world war.

The treatment of chronic ulcerative colitis was unsatisfactory, the best results being obtained by palliative measures. Most acute cases resolved spontaneously, though under stress they might always relapse. In acute cases with severe anæmia, blood-transfusion and liver injections were of great value; enemata of astringent solutions such as silver nitrate or tannic acid, or of eusol or acriflavine, had not proved beneficial, and in many cases were harmful. The sulphonamide drugs and penicillin were rarely helpful, and these again sometimes seemed to have a deleterious effect. The short-circuiting operations, such as ileostomy, appendicostomy, cæcostomy, and colostomy, had on the whole proved most unsatisfactory; and it was doubtful whether these were justifiable since acute colitis might continue below the opening, with the discharge of pus, mucus, and blood from the anus. The objections to these operations were: a considerable operative mortality, the psychological effect, and the probability of a permanent opening without material betterment of the patient's condition. Where total colectomy was done, there had been some entirely satisfactory results; and in carefully selected cases this operation might afford radical cure.

Dr. R. Winston Evans pointed out that the ileum was probably involved more often than was generally realised. The association of malignancy and ulcerative colitis was more frequent than could be expected from chance alone. Carcinoma usually developed in the younger patients, and the most common sites were the cæcum and the rectum.

". . . It is a fantastic anomaly that routine service of a domestic kind should have devolved upon trained nurses or even nurses *in training*. It would be equally wrong for day-to-day catering, purchasing, accountancy and general management to be undertaken by a medical man."—Dr. John Yule, *Public Health*, January, 1950, p. 55.

Reviews of Books

Further Rare Diseases and Debatable Subjects

Editor: F. PARKES WEBER, F.R.C.P. London: Staples Press. 1949. Pp. 236. 25*s.*

BECAUSE of his immense fund of knowledge and his experience of rare diseases, Dr. Parkes Weber has long been one of the best-known personalities in the medical world; and his enthusiasm and boyish delight in the unusual give an interest and a zest to his writings. A man who has already been a fellow of the Royal College of Physicians for over fifty years deserves special congratulations on this second and even fresher volume on rare diseases and debatable subjects, which he has produced with slight help from a few other authors. The subjects have a wide range, and though there is perhaps some bias towards the nervous system, the skin, and rheumatism, almost all varieties of disease are touched in one way or another. Indeed the diversity of his interests is astonishing. A few brief almost philosophical notes are there, and many groups of inborn developmental peculiarities are described. As in all Dr. Parkes Weber's writings, exact chapter and verse is given for every quoted opinion; but innumerable theories and ideas are scattered through the book. Interesting, stimulating, and (as the author says in his preface) instructive, the study of single cases can sometimes be as valuable as the study of large series. This volume, which is beautifully produced and illustrated, reflects high credit on its author and his collaborators.

Practical Anatomy

(2nd ed.) W. E. LE GROS CLARK, D.SC., F.R.S., F.R.C.S., professor of anatomy in the University of Oxford. London: Edward Arnold. 1949. Pp. 493. 30*s.*

OPPRESSED by the weight of topographical detail which his students of anatomy were expected to memorise, Prof. Le Gros Clark set out in 1946 to lighten their load by publishing a short dissecting manual. We commented [1] then on the need for an effort such as this, and wondered whether Prof. Le Gros Clark had gone far enough in following out his own views. The second edition (with its improved pictures, now numbering 268) will convince most readers that he has pruned as far as he can if every medical student is to dissect the entire body for himself. Some reformers of the anatomical curriculum, even more zealous in eliminating topographical detail than Prof. Le Gros Clark, may contend that most of the details even in this short book will soon be forgotten (and not subsequently missed) by that large body of medical students who enter general practice. But it will be a great pity if our future doctors do not dissect the whole body: the details may be forgotten, but the process leaves an intangible familiarity with the body's structure, and a respect for it which nothing less could cultivate. What a relief this splendid little book would have been to those who had to plough through the interminable prosiness of some former directions to would-be dissectors!

Female Sex Endocrinology

CHARLES H. BIRNBERG, M.D., associate obstetrician and chief of the female sex endocrinology laboratory, Jewish Hospital of Brooklyn. Philadelphia and London: J. B. Lippincott. 1949. Pp. 134. 35*s*

THE subject matter in this little book is useful and there are some excellent illustrations; the author knows his subject, has some original ideas, and has commendably condensed what he has to say. He covers the salient points about the commoner endocrine problems in the female, including those associated with adolescence, menstruation and its aberrations, the menopause, sterility, habitual abortion, and such oddments as mastalgia and hirsutism. In general his descriptions of the various conditions, if brief, are accurate, though there is one curious mis-statement where he describes the ovulatory mucus as "a thick, tenacious glairy plug . . . difficult to remove" and goes on to say that "as the cycle continues . . . the plug becomes thinner." His suggestions for treatment are mostly orthodox and clear. He rightly favours the cyclic and balanced use of the two ovarian hormones for such diverse conditions as amenorrhœa, dysmenorrhœa, menorrhagia, genital hypoplasia, and the induction of ovulation. The value of this type of therapy is perhaps not yet widely enough appreciated. The book rather falls down in the chapters on sterility and abortion: indeed the sketchy and inaccurate remarks about sterility in the male might with advantage have been omitted.

Human Relations in Modern Industry

R. F. TREDGOLD, M.A., M.D., D.P.M., regional psychiatrist, South Eastern Metropolitan Hospital Board; formerly Boots lecturer in industrial health, Roffey Park Rehabilitation Centre. London: Duckworth. 1949. Pp. 19 8*s.* 6*d.*

The Psychologist in Industry

M. E. STEINER, research psychologist, personnel division, General Electric Company, Bridgeport, Connecticut. Oxford: Blackwell Scientific Publications. 1949. Pp. 107. 9*s.* 6*d.*

IF Dr. Tredgold, quite properly in a book addressed to laymen, over-simplifies the integration of human relationships, Mr. Steiner regards men and society as existing merely to be measured. Both books are well worth reading; but the contrast in the British and the American approach to industrial relations is brought into sharp relief. Assuming that the well-being of men is paramount, Dr. Tredgold, through explanations of normal and abnormal psychological processes, proceeds to demonstrate the need to treat men as men, and, more important still, *how* to treat men as men. Elton Mayo's great contribution to the understanding of industrial morale, made by studying normal people, is emphasised; and in the closing chapters the British experiment in preventive reablement of the mentally ill at Roffey Park is described. The humanistic views are frank and refreshing, and set a goal both for those who manage industry and for those who manage hospitals.

Mr. Steiner's book contains useful accounts of the many psychometric procedures employed in estimating intelligence and aptitude. He is best when describing the Rorschach and similar tests; but whether the battery of tests to which an industrial worker may be subjected have real value in industry is not clearly stated. The importance of the psychometric approach to human relationships lies in the attempt to measure abilities even if (in contrast to Dr. Tredgold's humanistic integration) this results in a purely technical approach. Paradoxically, the greatest danger to the future industrial worker may be the numerous and complex tests designed to ensure his correct placement: efficiency becomes the measure of health. For those interested in psychometric procedures, the book will prove a useful summary; but Mr. Steiner damages his own case by advocating counselling (perilously close to therapy) by non-medically qualified psychologists.

Fundamental Considerations in Anesthesia

CHARLES L. BURSTEIN, M.D., chief, department of anesthesiology, Hospital for Special Surgery; attending consultant in anesthesia, Veterans Administration Hospital, Bronx, N.Y. New York and London: Macmillan. 1949. Pp. 153. 30*s.*

NOWADAYS onlookers find it difficult to follow the reasoning behind the complex mixtures of drugs administered during anæsthesia, and to explain some of the phenomena encountered. Dr. Burstein's little book attempts to explain why things happen. He introduces, as he must, a certain amount of physiology and pharmacology, both important subjects for any real understanding of anæsthesia. Much of the book is devoted to a discussion of the effect, on the autonomic nervous system, and in particular on the respiration and circulation, of a combination of anæsthetic drugs and surgical trauma. Laryngeal spasm, and the effect of stimuli and of drugs on the cœliac plexus and on the carotid sinus, are considered in detail. The text is well illustrated with helpful diagrams and tracings from the author's own experimental work. His style is a little stilted, but he demonstrates in a telling and learned manner that if anæsthetists are to be something more than knob-turners they must have a basic knowledge of physiology and pharmacology.

THE LANCET

LONDON: SATURDAY, JAN. 28, 1950

Sulphones in Leprosy and Tuberculosis

Leprosy is not a rapidly fatal disease, and even in such countries as India it is of less biological mportance than tuberculosis. Nevertheless it has always provoked horror, and, largely because it lasts so long, it causes an immense amount of suffering. The British Commonwealth contains a large proportion of all cases of leprosy, and we should therefore be especially concerned to improve the treatment of this ntractable infection.

It is nearly a century since Mouat[1] in 1854 gave the first English description of the use of chaulmoogra oil; and this oil can perhaps be regarded as the first example of a remedy with a direct antibacterial action, since intravenous injection of its derivatives is followed by disintegration of leprosy bacilli.[2] Quite possibly chaulmoogra will retain a place in association with other agents[3]; but it is fair to say that interest has now shifted to synthetic drugs and particularly to the derivatives of 4 : 4′ diamino-diphenyl sulphone, which Buttle et al.[4] introduced into therapeutics in 1937 under the name of diaminosulphone. These derivatives, such as ‘Promin,’ ‘Diasone’ and ‘Sulphetrone,’ are less toxic, and have therefore been considered better therapeutic agents than the parent substance; but the advantage of using them has been challenged.[5] If, as is now suggested, their activity is due to the diaminosulphone which they liberate in the body, the question arises whether the same effect cannot be obtained by giving this drug itself instead of its derivatives. Cannot the objection to its high toxicity be met by merely reducing its dose? Admittedly it has been found 15 times as toxic to mice as sulphanilamide, but it was also 30 times as active against streptococci—i.e., it had a therapeutic index twice as high.[6] In bovines it is actually less toxic than sulphanilamide—a fact which has led to its use in the treatment of mastitis in cattle. A recent investigation of its antibacterial and pharmacological properties[7] has, we understand, been followed by experimental studies[8] showing that in mice, to produce the same effects as diaminosulphone against streptococcal infection, 5–6 times as much promin and diasone, and nearly 100 times as much sulphetrone, had to be added to the diet. It is now, indeed, widely accepted that both the activity, and most of the toxicity, of the solubilised derivatives of diaminosulphone depend on the extent to which they break down into the parent drug. Incorporated in the diet at a concentration of 0·1 or 0·025%, the latter has proved slightly more effective against rat-leprosy than streptomycin.[8]

On the clinical side Cochrane and colleagues[9] have accumulated evidence indicating that diaminosulphone, in a 25% suspension of arachis oil injected subcutaneously, is the most potent agent available against leprosy. Toxic reactions were observed in some patients, but the drug seems to have been tolerated in doses not exceeding 1–1·5 g. weekly. Molesworth and Narayanaswami[10] have likewise obtained favourable results, using smaller doses of the suspension, without any serious toxic effects. In Nigeria, Smith[11] has shown that the drug is well absorbed in man, 83% of the daily oral intake being recoverable from the urine; and, as excretion is slow, a single daily dose of 300 mg. gives blood-levels of at least 1·0 mg. per 100 ml. Recording fresh observations in our present issue, Dr. Lowe recommends oral administration of small doses, rising in five weeks from 100 mg. to the standard 300 mg. daily. This régime, he says, has given excellent results in lepromatous and tuberculoid leprosy, and the small doses of diaminosulphone have proved to be at least as effective as much larger doses of the complex sulphones. Similar success has been reported by Floch and Destombes[12] using no more than 200 mg. a day. All this is important particularly because diaminosulphone is so much cheaper than its derivatives: the amount that is needed for Lowe's modified régime of twice-weekly oral doses for out-patients costs only 7*s.* per patient a year—a sum which could well be found even for moneyless native patients numbering millions. With a remedy so inexpensive and apparently so effective, leprosy may be the first of the great infectious diseases to be brought under control largely by chemotherapy.

Dr. Lowe suggests that the use of diaminosulphone in the treatment of human tuberculosis should now be re-examined. Though Pfeutze and Pyle[13] conclude that its derivatives, promin and diasone, have some action in certain forms of tuberculosis, it seems unlikely that we can expect much from the use of any of these drugs alone. On the other hand, they may have the same action as *p*-aminosalicylic acid in preventing the development of streptomycin resistance[14]—and in much smaller doses. Various workers have claimed that in experimental tuberculosis the results are better when *p*-aminosalicylic acid or one of the sulphones is given with streptomycin than when streptomycin is given alone. Moeschlin and Schreiner[15] provide fairly convincing evidence to support this opinion, and so do Rist and Cottet,[16] who describe clinical tests carried out with Brissaud and Cousin in cases of tuberculous meningitis, where the effects of streptomycin were compared with those of streptomycin plus the sulphone given both intrathecally and by mouth. The advantage of the combined treatment seemed to lie not in the rapidity of cure but in the reduction of deaths during the 4th–6th month, most of which are associated with the appearance of resistant bacilli. The investigators noted that children under six years of age tolerated diaminodiphenyl sulphone in doses of 4 mg. daily per kg. body-weight, or even 5 mg., whereas older children tolerated no more than 3 mg. It remains to be seen whether, in small doses, the drug will be as useful as *p*-aminosalicylic acid as an adjuvant to streptomycin.

Leucotomy for Pain

SINCE Prof. WALTER FREEMAN[1] began to extend the field of prefrontal leucotomy to the treatment of intractable pain in non-psychotic patients, the operation has probably been performed for this purpose by many surgeons all over the world. But as it is generally regarded as a last resort after other therapeutic procedures (psychotherapy, nerve block, nerve section, drug and sleep therapy, shock therapy, sympathectomy, chordotomy, &c.) have failed, the number of cases treated by one neurosurgeon must naturally be small; hence the scarcity of reports on representative series. The indications for the operation, and the effects to be expected from it, have been clarified by the American papers published in the last two years, but these have also revealed some unsolved problems in regard to the mechanism of the results and their theoretical implications.

The operation can undoubtedly relieve the pain of incurable cancer. OTENASEK,[2] at Johns Hopkins, for example, describes its use in 11 patients requiring heavy doses of analgesics and narcotics, and, except for one whose death was attributable to the leucotomy, all of them were freed from pain and suffering until the time of the report or until they died from cancer. At the Lahey Clinic in Boston, where this treatment was started in 1946,[3] DYNES and POPPEN[4] have now reported on their results in 18 patients. Half of these had malignant metastases and the remainder various other severely painful conditions, such as neuralgias or tabetic crises. All had received large amounts of morphine and other analgesics, and many were addicts. Several had undergone other operative procedures such as rhizotomy or chordotomy without improvement. The results of leucotomy were "good" in 11 cases and "fair" in 4; in 3 cases the result was "poor," but 2 of these patients were cured of their narcotic addiction. On the whole, the response was best in the cancer cases. At both Johns Hopkins and the Lahey Clinic the operation performed was a bilateral leucotomy. To avoid undesirable personality changes, SCARFF[5] operated on one hemisphere only in 33 patients. Again those with neoplasms formed the majority, but he also included patients with phantom-limb pain and arthritis. Though he performed a very thorough severance of white fibres under direct visual control, his results—good in 22 cases, fair in 6, and poor in 5—seem less favourable, and the relief of pain less definite, than with the bilateral operation. There was no evidence that an ipsilateral leucotomy was more effective if the pain was localised to one side of the body or that the results were any better if the dominant hemisphere was operated on. In assessing the results malignant cases the duration of observation operation is important. Good results lastin two years are among those cited, but in mar best cases the follow-up period is only a few Even so, in several patients immediate relief followed by a return of symptoms, paralle relapse of mental symptoms observed i psychotic patients after leucotomy.

The patient's subjective reaction to the op is not always as expected. Some feel com relieved and never complain of pain after the tion; but it is more common to find that the p will admit when questioned that the pain has per though they no longer make any spontaneous plaint. Their demeanour and behaviour gi indication that they are suffering. Moreover desire for drugs and the addiction to analg invariably cease, even in the apparently less favou cases; anxiety disappears, and, in the malignant the fear of impending death is replaced by c ful equanimity. These psychological effects a special interest in view of CHAPMAN'S[6] parado observation that when the pain threshold of patients is determined by quantitative methods are found to be oversensitive to painful stimu the skin after the operation. The most plau explanation of the action of leucotomy is still th abolishes suffering rather than pain, removing emotional component and distressing significa The important question whether "primary" d addiction, not due to or ascribed to bodily p should be treated by leucotomy can hardly answered in general terms. Everything depends the original personality of the addict, his stabil his social and occupational adaptation, and the mo support he can expect from his family. The tenden for the patient after the operation to become l self-critical, with weakened will-power and se restraint and a reduced sense of responsibility, w deter the psychiatrist from recommending leucotom in most of these cases.

One had hoped and still may hope that research into the effects of leucotomy in non-psychotic subject may teach us something about the influence of frontal lobe damage on personality, which is often difficult to discern in the mentally disturbed. Even the simple question of whether the beneficial results can be obtained without sacrificing personality assets is not answered by the present observations. SCARFF'S unilateral-leucotomy patients underwent psychometric tests and their intellectual abilities were found to be unchanged, but many workers have made the same claim for the bilateral operation. His estimate of personality change can hardly be regarded as reliable in view of the short period of postoperative observation. The two reports on bilateral leucotomy give one the impression that the relief of pain depends on alterations in the emotional aspects of personality. DYNES and POPPEN classify their cases as either "retarded" or "euphoric" after operation—obviously an oversimplification of a complex and fluctuating clinical change. It is reasonable to assume that personality changes are quantitatively related to the extent of frontal-lobe isolation, but we still o not know how great this must be to abolish intract- ble pain without sacrificing assets of personality. n cases of malignant disease this may be of little onsequence, but it must limit the application of he operation in patients whose pain is not caused by terminal illness.

Cortisone, A.C.T.H., and Deoxycortone

Hench's dramatic report on 'Cortisone' in rheumatoid arthritis has opened an entirely new field of work, and results are being obtained which could not have been foretold. Their importance, as we have already suggested, lies more in their potentialities than in any method of treatment so far devised: Spies and Stone[1] rightly describe the adrenocorticotropic hormone (A.C.T.H.) as a tool of research. As McNee[2] indicates, long-continued therapy with cortisone or A.C.T.H. carries serious risks; and it is necessary to point out that a plentiful supply of these compounds would not mean the "cure" of rheumatoid arthritis in general. The range of conditions found susceptible to treatment is steadily increasing: Elkinton and his colleagues[3] have confirmed the previous results with A.C.T.H. in rheumatoid arthritis and rheumatic fever and have obtained remissions in disseminated lupus erythematosus, dermatomyositis, and status asthmaticus: Baehr[4] has likewise noted remission in lupus erythematosus, and Pearson, Eliel, and Talbot[5] describe diminution in the size of the spleen and lymph-glands in chronic lymphatic leukæmia, lymphosarcoma, and Hodgkin's disease, and a remission in five cases of acute leukæmia. But Elkinton had to discontinue treatment of one rheumatoid patient because of the development of Cushing's syndrome—a complication also referred to by Baehr—and on cessation of treatment the acute rheumatoid symptoms returned in their original intensity. Another patient showed the symptoms of alkalosis and low potassium associated with hypercorticaladrenalism, and another apparently became refractory to the drug.

The action of the compounds seems to be a general one on the connective tissues of the body, and Ragan[6] says that in patients under treatment with A.C.T.H. there is inhibition of growth of granulation tissue in open wounds and delay of healing in incised wounds: he suggests that cortisone and A.C.T.H. may act by decreasing reactivity of connective tissue to trauma of unknown origin. The fact that the disorders benefited are not associated with the usual symptoms of adrenal insufficiency led Marrian and his colleagues[7] to wonder whether they might be due to an abnormal metabolism of cortisone, rather than to a primarily insufficient supply; they therefore studied the metabolism of a related hormone, progesterone, in rheumatoid patients and found that a much higher proportion than normal was excreted as pregnanediol. This is definite evidence of some abnormality of steroid metabolism, but Marrian wisely takes a very cautious view of its meaning, and does not claim that it has necessarily any bearing on the effect of cortisone. Fitch, Warter, and Seifter[8] now report good results in mild or acute rheumatoid arthritis with "artistone" (21-acetoxypregnenolone) derived from plant sources (steroidal saprogenin). Seifter's ingenious experimental method of testing anti-arthritic properties, developed from the work of Selye and of Ragan and Meyer, has revealed eight other sterol compounds considered promising.

On the chemical side progress is being made apace. Li[9] has shown that comparatively simple polypeptides with adrenocorticotropic activity can be prepared by partial hydrolysis of the ordinary protein A.C.T.H., and in our last issue Dr. and Mrs. C. J. O. R. Morris reported the isolation of a polypeptide (A.C.T.P.) which has, weight for weight, ten times the activity of A.C.T.H. The Nuffield Foundation grants to Cambridge for investigations on A.C.T.H., and to Oxford for study of the synthesis of cortisone and related compounds, should aid further advance.

Arising out of the work on cortisone came the claim by Lewin and Wassén[10] that signs and symptoms in rheumatoid arthritis are removed or reduced by the use of deoxycortone and ascorbic acid in association with one another. Attempts to repeat this observation have led to numerous provisional reports in our columns, some confirming and others denying the the effect. On Nov. 26 we said it was difficult to reconcile it with Selye's work on formalin arthritis in rats: but the paper by Dr. Brownlee, which we publish this week, goes a long way towards bringing the two sets of findings together. Brownlee found that daily doses of deoxycortone with ascorbic acid protected both normal and adrenalectomised rats against formalin arthritis; but, whereas ascorbic acid alone offers some slight protection to normal rats, deoxycortone exacerbates the condition. In adrenalectomised animals ascorbic acid alone has no effect and deoxycortone a much smaller one. At the moment the interpretation of this must be somewhat speculative.

Control of Drugs

In 1948 the total production of soporific drugs in the U.S.A. amounted to 336 tons—the equivalent of about 24 therapeutic doses for each person in the country. The World Health Organisation's expert committee on habit-forming drugs was told this when it met in Geneva this month to consider which drugs should be included by the United Nations in the international conventions which provide for control. Control of synthetic drugs falls within the scope of the 1948 Paris protocol, which came into force on Dec. 1 last year; and one of the new synthetic substances on which the committee heard evidence was a potent analgesic, known as 'Keto-Bemidone,' which has been found particularly liable to produce addiction. This drug belongs to the pethidine group, several members of which the committee had already recommended for control. The committee reiterated its concern over the increased consumption of diamorphine in several countries. In Finland consumption per million inhabitants rose from 6·98 kg. in 1936 to 17·67 kg. in 1947; but it fell slightly to 16·68 kg. in 1948, and the Finnish government estimates that this year it will be 5 kg. In Italy the figure increased from 3·4 kg. in 1936 to 5 kg. in 1947, but fell slightly to 4·26 kg. in 1948.

SOME ACTIONS OF CHLORAMPHENICOL

With our small supplies of the new antibiotics, 'Aureomycin' and chloramphenicol, it has not been possible in this country to obtain first-hand evidence of their usefulness except in a very limited number of infections. Their activity against systemic infections with gram-negative bacteria has been demonstrated in the clinical response of typhoid fever to chloramphenicol, and the response of brucellosis to both drugs; so there was good reason for testing them against *Hæmophilus pertussis*, which is sensitive in vitro to very low concentrations of aureomycin or chloramphenicol.

In experimental infections with *H. pertussis*, aureomycin has proved effective in mice inoculated intracerebrally,[1] and chloromycetin in mice infected intranasally (so far unpublished), but very few clinical trials have been reported. Bell and his colleagues [1] have had encouraging results with aureomycin in 20 children with whooping-cough, more particularly in cases which were treated early. Payne and his co-workers [2] have given chloramphenicol in 50 severe cases in children aged 0–9 years, and found that fever, when present, disappeared on the second day of treatment and that paroxysms of coughing decreased from the third day and usually disappeared by the sixth day, leaving only a "light cough" for a few more days. They obtained good results with rectal and intravenous as well as oral administration of the drug. In this issue Dr. Gray reports good results with chloramphenicol among out-patient children whose progress was assessed from cough-counts (the number of paroxysms of coughing per 24 hours) made by the mothers. The cases were divided at the start of treatment into early or late, according to whether they were in the first or second fortnight of the infection, and alternate patients received chloramphenicol or similar capsules of milk-sugar by mouth. In both groups the treated children showed a rapid reduction in the cough-counts within 4–8 days; whooping and vomiting quickly disappeared, and the harsh hacking cough was replaced by a soft exudative cough more like that of bronchitis. In the controls, the cough-charts show, the recovery was decidedly slower. Any new claim for cure of a disease which has had so many "cures" must be received with caution, but the results with chloramphenicol certainly justify large-scale controlled trials under hospital supervision, and the Medical Research Council, through its antibiotics (non-tuberculous infections) committee, is understood to be already organising such trials in centres throughout the country. The difficulties to be overcome, besides those inherent in any controlled therapeutic trial, include the early recognition of the infection by the practitioner, the persuasion of doctor and parent that hospital treatment is often best for a young child with pertussis, and sufficient supplies of isolation accommodation and trained nurses. Gray also discussed the difficulty of giving children aged 1–3 years an intensely bitter drug like chloramphenicol by mouth. Rectal administration he found to be ineffective, and his only answer at the moment seems to be a stomach-tube; rather than agree to this, many mothers would manage somehow to get powders or capsules down, disguised in jam or syrup, or, as Payne and his colleagues found successful, in honey or orange juice. These American workers also treated 6 cases with rectal suppositories, and 5 cases with intravenous injections of a solution in propylene glycol, and these 11 children were all free of symptoms in five days or less. Gray's dosage for children, established during the trial, was 100 mg. per kg. of bo weight as a loading dose, followed by three-ho maintenance doses of 60 mg. up to the age of 1 y 125 mg. at 1–3 years, and 250 mg. after this age. (of his patients had a short allergic reaction to her f dose, presumably because she was sensitive to so *bacterial* product. Perhaps the main interest in Gra paper lies in the experiments that arose out of his clin trial. He found that the older children under treatm developed a curious weakness of accommodatio print rapidly became blurred when they were readi and vision would recover temporarily after a sh rest. By weight-holding tests Gray showed that ad show a similar weakness of skeletal muscles, as well as accommodation.

What may turn out to be an observation of f reaching significance is that chloramphenicol kills all the bacterial flora of the upper respiratory muco membrane. Gray's serial nasal swabs showed th massive bacterial death, usually amounting to complet sterilisation, occurs within an hour of a single dos The sterility continues for 3–5 days after the end of course of the drug, and it can probably be maintain for as long as is desired by continuing or repeating course. This finding obviously calls for further inqui How far does the sterilisation extend down the respirat tract? And is there any similar effect on the intesti *flora*?

X-RAY CINEMATOGRAPHY

Good angiocardiography has become essential in diagnosis of cardiac lesions, especially in *congen* heart-disease. There are three different ways of obta ing pictures of a radio-opaque substance as it pas through the great vessels and the chambers of the hea These are: (1) ciné-camera photography of a fluo scopic screen, (2) serial radiography using a rap changing device, and (3) roll-film radiography. T method which so far seems to have gained most popular in this country is that employing the rapid chang of cassettes. This has obvious disadvantages: heavy and bulky containers are difficult to feed rapi past the patient; they use an expensive amount film; and the noise is quite alarming. Results fr roll-film photography have lately been described Campbell and Hills,[1] who took serial pictures at o second intervals by a technique [2] adapted from that u in mass radiography. This technique has the merit being relatively inexpensive. Roll-film radiography moreover, a little neater and faster than serial rad graphy; but, judging by the standard at the Bar Hospital, St. Louis, it is no less noisy. In this investi tion adult patients are rarely given an anæsthe so anything that may diminish the ordeal for them welcome.

Cinematography may well prove to be the method choice if sufficient speeds can be obtained; and in t issue Professor Janker, of Bonn, describes how he l succeeded in perfecting a technique for use in ma Professor Janker may be regarded as a pioneer X-ray cinematography; as long ago as 1932 he publis accounts of this type of work in animals.[3] In this coun Prof. K. J. Franklin [4] utilised the technique for a stu of blood-flow in the great veins, and as a result so beautiful cardiovascular studies have emanated from t Nuffield Institute for Medical Research at Oxford.[5]

When a ciné film is projected, the minimum spe which avoids visual flicker is 16 frames per secon the rate of photography should be not less than t or it is not true cinematography. Professor Janke hod employs 18, and occasionally 24, frames per nd with a skin exposure of about 50 röntgen in a iod of 6–8 seconds. Subsequently, each photograph opied up to twenty times, and thus when the film iewed the whole process is slowed down and can be died more closely. Professor Janker uses as a trast medium 70% or 80% organic iodide of which -60 ml. is injected into an arm vein in 1–2 seconds ; this part of the method is much the same as when settes or roll film are used. The illustration accom-nying Professor Janker's article gives some idea of the cellent definition obtained with X-ray cinematography d also of the information which such pictures can er to the physician in diagnosis and to the surgeon in anning an operation. Indeed, this is the only tech-que which allows one to see the blood, or rather a dio-opaque substance, actually flowing through the art.

APPROVED SCHOOLS

AMONG possible economies being considered in these ard times is a saving on approved schools. The Select ommittee on Estimates have therefore been trying to ecide whether such schools are doing their job.[1] There re 162 approved schools in England and Wales, 124 of hem run by voluntary bodies ; and in Scotland there are 25 schools, all but 1 of them voluntary. There are advantages in both types, the committee think: voluntary societies have a long and good tradition, many of them have a religious background, and their staffs believe that voluntary bodies encourage initiative in headmasters; on the other hand, such schools may be out of the general current of public life, whereas local-government schools are not. The record of success is moderately good. In England and Wales 66% of successes are claimed among the boys and 80% among the girls ; in Scotland the figures are rather better—76·3% for boys and 93·6% for girls. The committee were well satisfied, on the whole, with the conditions in the five schools which they visited ; but they describe one unsuitable and gloomy place where the children were poorly dressed, the atmosphere oppressive, and the gymnasium closed to them in their spare time, the only recreation-rooms being the classrooms. They recommend that conditions here should be remedied with the least possible delay.

Approved schools are expensive ; the weekly cost for senior boys ranges from £3 17*s*. 8*d*. to £9 12*s*. 7*d*. ; for girls it ranges from £3 0*s*. 3*d*. to £6 16*s*. 9*d*. This is doubtless partly due to the need for a relatively high ratio of staff to children. Approved schools are open all the year round, and as the children's leisure, like their school hours, is a learning time, the number of teachers cannot be reduced if results are to be maintained and improved. On the other hand the number of children being admitted has declined year by year since the end of the war—for what reasons we are not told in this report—and it seems that some of the senior girls' schools are to be closed. The committee advise that the possibility of closing more schools should be kept under review.

They suggest no major change in the present dual management of school, by voluntary and statutory bodies, but they think that efficiency would be greater if local government was represented on all voluntary management boards. They also think that foster-care might be used more widely as an alternative to approved-school training. Classifying schools, in which children are studied before being sent to the most appropriate approved schools, have proved very successful. These only cover the needs of half the country at present, and the committee favour the provision of more classifying schools, believing that by their use the time some children spend in an approved school might be reduced. They hold that facilities for practical training should be introduced where they do not already exist, and should be related as closely as possible to outside apprenticeship and vocational requirements. Altogether it looks as though we cannot save much here : the money spent on approved schools is in the main well spent.

POST-WAR RESEARCH

IN the years following the end of the war the activities of the Medical Research Council fell broadly into three phases : contraction, reorientation, and expansion. The council's report on these years[1] opens with a brief epitaph on its short-term investigations during the war[2] :

> "It may be said here, in retrospect, that when the fundamental knowledge available was already substantial, investigations of this type generally led to satisfactory solutions of immediate value ; but that when fundamental knowledge was inadequate, as in the case of wound shock, for example, the additional information gained under wartime conditions did not generally provide a basis for complete control, although the results often gave useful practical help of a limited kind. This is a lesson of great significance in planning for the future."

Among the war-time committees which have been disbanded are those concerned with war wounds, clinical trials and synthesis of penicillin, brain injuries, traumatic shock, malaria, typhus, therapeutic requirements, and military personnel research. Though the brain-injuries committee no longer functions, the cognate committee on nerve injuries remains in being, as also do the food-rationing (special diets) advisory committee and the Royal Naval personnel research committee ; but the largest war-time activity carried over into peace is the operation, on behalf of the Ministry of Health, of the Public Health Laboratory Service.

For research-workers the personal reorientation to peace-time conditions was not easy.

> "In other cases, especially among the leaders, the change to be faced was even greater, because those who were controlling and directing other men engaged on wartime problems had little time to engage personally in research. These men have had to re-adapt their lives, and, after working in gregarious conditions while helping others in the practical solution of war problems, have had to settle down again to the laboratory bench with entirely different problems to study."

The council itself has been faced with shortages of accommodation, of equipment, and also of trained men. This last shortage is attributed to the long gap in recruitment, and to a lesser extent to war casualties ; and "added to this is the competition of other expanding medical and scientific services for the limited man-power available." Among the main preoccupations of the council, occupational health and nuclear physics have taken an increasingly prominent place ; and new research units have been set up as follows : a pneumoconiosis unit at Cardiff, an industrial-medicine unit at Birmingham, blood-products, blood-group, and blood-transfusion units in London, a dental unit in London, a clinical chemotherapeutic unit at Glasgow, a clinical endocrinological unit at Edinburgh, an electromedical unit at Stoke Mandeville, a building unit in London, a toxicology unit at Porton, a biophysics unit in London, a radiobiological unit at Harwell, a vision unit in London, a unit on the molecular structure of biological systems at Cambridge, a social-medicine unit in London, and a unit on climate and working efficiency at Oxford.

The cost of instituting these units and of expanding the council's other establishments, including the National

SOME ACTIONS OF CHLORAMPHENICOL

WITH our small supplies of the new antibiotics, 'Aureomycin' and chloramphenicol, it has not been possible in this country to obtain first-hand evidence of their usefulness except in a very limited number of infections. Their activity against systemic infections with gram-negative bacteria has been demonstrated in the clinical response of typhoid fever to chloramphenicol, and the response of brucellosis to both drugs; so there was good reason for testing them against *Hæmophilus pertussis*, which is sensitive in vitro to very low concentrations of aureomycin or chloramphenicol.

In experimental infections with *H. pertussis*, aureomycin has proved effective in mice inoculated intracerebrally,[1] and chloromycetin in mice infected intranasally (so far unpublished), but very few clinical trials have been reported. Bell and his colleagues [1] have had encouraging results with aureomycin in 20 children with whooping-cough, more particularly in cases which were treated early. Payne and his co-workers [2] have given chloramphenicol in 50 severe cases in children aged 0–9 years, and found that fever, when present, disappeared on the second day of treatment and that paroxysms of coughing decreased from the third day and usually disappeared by the sixth day, leaving only a "light cough" for a few more days. They obtained good results with rectal and intravenous as well as oral administration of the drug. In this issue Dr. Gray reports good results with chloramphenicol among out-patient children whose progress was assessed from cough-counts (the number of paroxysms of coughing per 24 hours) made by the mothers. The cases were divided at the start of treatment into early or late, according to whether they were in the first or second fortnight of the infection, and alternate patients received chloramphenicol or similar capsules of milk-sugar by mouth. In both groups the treated children showed a rapid reduction in the cough-counts within 4–8 days; whooping and vomiting quickly disappeared, and the harsh hacking cough was replaced by a soft exudative cough more like that of bronchitis. In the controls, the cough-charts show, the recovery was decidedly slower. Any new claim for cure of a disease which has had so many "cures" must be received with caution, but the results with chloramphenicol certainly justify large-scale controlled trials under hospital supervision, and the Medical Research Council, through its antibiotics (non-tuberculous infections) committee, is understood to be already organising such trials in centres throughout the country. The difficulties to be overcome, besides those inherent in any controlled therapeutic trial, include the early recognition of the infection by the practitioner, the persuasion of doctor and parent that hospital treatment is often best for a young child with pertussis, and sufficient supplies of isolation accommodation and trained nurses. Gray also discussed the difficulty of giving children aged 1–3 years an intensely bitter drug like chloramphenicol by mouth. Rectal administration he found to be ineffective, and his only answer at the moment seems to be a stomach-tube; rather than agree to this, many mothers would manage somehow to get powders or capsules down, disguised in jam or syrup, or, as Payne and his colleagues found successful, in honey or orange juice. These American workers also treated 6 cases with rectal suppositories, and 5 cases with intravenous injections of a solution in propylene glycol, and these 11 children were all free of symptoms in five days or less. Gray's dosage for children, established during the trial, was 100 mg. per kg. of bo weight as a loading dose, followed by three-hou maintenance doses of 60 mg. up to the age of 1 ye 125 mg. at 1–3 years, and 250 mg. after this age. O of his patients had a short allergic reaction to her fi dose, presumably because she was sensitive to so bacterial product. Perhaps the main interest in Gray paper lies in the experiments that arose out of his cli trial. He found that the older children under treatme developed a curious weakness of accommodatio print rapidly became blurred when they were readin and vision would recover temporarily after a sho rest. By weight-holding tests Gray showed that adult show a similar weakness of skeletal muscles, as well as accommodation.

What may turn out to be an observation of far reaching significance is that chloramphenicol kills o all the bacterial flora of the upper respiratory mucou membrane. Gray's serial nasal swabs showed that massive bacterial death, usually amounting to complete sterilisation, occurs within an hour of a single dose The sterility continues for 3–5 days after the end of course of the drug, and it can probably be maintaine for as long as is desired by continuing or repeating th course. This finding obviously calls for further inquir How far does the sterilisation extend down the respirato tract ? And is there any similar effect on the intestin flora ?

X-RAY CINEMATOGRAPHY

GOOD angiocardiography has become essential in t diagnosis of cardiac lesions, especially in congenit heart-disease. There are three different ways of obtai ing pictures of a radio-opaque substance as it pass through the great vessels and the chambers of the hea These are: (1) ciné-camera photography of a fluor scopic screen, (2) serial radiography using a rapi changing device, and (3) roll-film radiography. T method which so far seems to have gained most populari in this country is that employing the rapid changi of cassettes. This has obvious disadvantages: t heavy and bulky containers are difficult to feed rapid past the patient; they use an expensive amount film; and the noise is quite alarming. Results fro roll-film photography have lately been described l Campbell and Hills,[1] who took serial pictures at on second intervals by a technique [2] adapted from that use in mass radiography. This technique has the merit o being relatively inexpensive. Roll-film radiography i moreover, a little neater and faster than serial radi graphy; but, judging by the standard at the Barn Hospital, St. Louis, it is no less noisy. In this investig tion adult patients are rarely given an anæstheti so anything that may diminish the ordeal for them welcome.

Cinematography may well prove to be the method choice if sufficient speeds can be obtained; and in th issue Professor Janker, of Bonn, describes how he h succeeded in perfecting a technique for use in ma Professor Janker may be regarded as a pioneer X-ray cinematography; as long ago as 1932 he publish accounts of this type of work in animals.[3] In this count Prof. K. J. Franklin [4] utilised the technique for a stu of blood-flow in the great veins, and as a result so beautiful cardiovascular studies have emanated from th Nuffield Institute for Medical Research at Oxford.[5]

When a ciné film is projected, the minimum spe which avoids visual flicker is 16 frames per second the rate of photography should be not less than th or it is not true cinematography. Professor Janke

ıod employs 18, and occasionally 24, frames per ıd with a skin exposure of about 50 röntgen in a ɔd of 6–8 seconds. Subsequently, each photograph ɔpied up to twenty times, and thus when the film ewed the whole process is slowed down and can be ied more closely. Professor Janker uses as a rast medium 70% or 80% organic iodide of which 30 ml. is injected into an arm vein in 1–2 seconds; his part of the method is much the same as when ettes or roll film are used. The illustration accompying Professor Janker's article gives some idea of the ellent definition obtained with X-ray cinematography also of the information which such pictures can r to the physician in diagnosis and to the surgeon in nning an operation. Indeed, this is the only techue which allows one to see the blood, or rather a io-opaque substance, actually flowing through the rt.

APPROVED SCHOOLS

AMONG possible economies being considered in these d times is a saving on approved schools. The Select mmittee on Estimates have therefore been trying to ide whether such schools are doing their job.[1] There 162 approved schools in England and Wales, 124 of m run by voluntary bodies; and in Scotland there are schools, all but 1 of them voluntary. There are vantages in both types, the committee think: luntary societies have a long and good tradition, ny of them have a religious background, and their ffs believe that voluntary bodies encourage initiative headmasters; on the other hand, such schools may be t of the general current of public life, whereas localvernment schools are not. The record of success is derately good. In England and Wales 66% of ccesses are claimed among the boys and 80% among the ls; in Scotland the figures are rather better—76·3% r boys and 93·6% for girls. The committee were ell satisfied, on the whole, with the conditions in the e schools which they visited; but they describe one suitable and gloomy place where the children were orly dressed, the atmosphere oppressive, and the mnasium closed to them in their spare time, the ly recreation-rooms being the classrooms. They commend that conditions here should be remedied ith the least possible delay.

Approved schools are expensive; the weekly cost for nior boys ranges from £3 17*s.* 8*d.* to £9 12*s.* 7*d.*; for irls it ranges from £3 0*s.* 3*d.* to £6 16*s.* 9*d.* This is oubtless partly due to the need for a relatively high tio of staff to children. Approved schools are open all e year round, and as the children's leisure, like their hool hours, is a learning time, the number of teachers nnot be reduced if results are to be maintained and proved. On the other hand the number of children eing admitted has declined year by year since the end f the war—for what reasons we are not told in this report -and it seems that some of the senior girls' schools are be closed. The committee advise that the possibility f closing more schools should be kept under review.

They suggest no major change in the present dual anagement of school, by voluntary and statutory odies; but they think that efficiency would be greater local government was represented on all voluntary anagement boards. They also think that fosterare might be used more widely as an alternative to pproved-school training. Classifying schools, in which hildren are studied before being sent to the most ppropriate approved schools, have proved very uccessful. These only cover the needs of half the ountry at present, and the committee favour the rovision of more classifying schools, believing that by their use the time some children spend in an approved school might be reduced. They hold that facilities for practical training should be introduced where they do not already exist, and should be related as closely as possible to outside apprenticeship and vocational requirements. Altogether it looks as though we cannot save much here: the money spent on approved schools is in the main well spent.

POST-WAR RESEARCH

IN the years following the end of the war the activities of the Medical Research Council fell broadly into three phases: contraction, reorientation, and expansion. The council's report on these years[1] opens with a brief epitaph on its short-term investigations during the war[2]:

> "It may be said here, in retrospect, that when the fundamental knowledge available was already substantial, investigations of this type generally led to satisfactory solutions of immediate value; but that when fundamental knowledge was inadequate, as in the case of wound shock, for example, the additional information gained under wartime conditions did not generally provide a basis for complete control, although the results often gave useful practical help of a limited kind. This is a lesson of great significance in planning for the future."

Among the war-time committees which have been disbanded are those concerned with war wounds, clinical trials and synthesis of penicillin, brain injuries, traumatic shock, malaria, typhus, therapeutic requirements, and military personnel research. Though the brain-injuries committee no longer functions, the cognate committee on nerve injuries remains in being, as also do the food-rationing (special diets) advisory committee and the Royal Naval personnel research committee; but the largest war-time activity carried over into peace is the operation, on behalf of the Ministry of Health, of the Public Health Laboratory Service.

For research-workers the personal reorientation to peace-time conditions was not easy.

> "In other cases, especially among the leaders, the change to be faced was even greater, because those who were controlling and directing other men engaged on wartime problems had little time to engage personally in research. These men have had to re-adapt their lives, and, after working in gregarious conditions while helping others in the practical solution of war problems, have had to settle down again to the laboratory bench with entirely different problems to study."

The council itself has been faced with shortages of accommodation, of equipment, and also of trained men. This last shortage is attributed to the long gap in recruitment, and to a lesser extent to war casualties; and "added to this is the competition of other expanding medical and scientific services for the limited man-power available." Among the main preoccupations of the council, occupational health and nuclear physics have taken an increasingly prominent place; and new research units have been set up as follows: a pneumoconiosis unit at Cardiff, an industrial-medicine unit at Birmingham, blood-products, blood-group, and blood-transfusion units in London, a dental unit in London, a clinical chemotherapeutic unit at Glasgow, a clinical endocrinological unit at Edinburgh, an electromedical unit at Stoke Mandeville, a building unit in London, a toxicology unit at Porton, a biophysics unit in London, a radiobiological unit at Harwell, a vision unit in London, a unit on the molecular structure of biological systems at Cambridge, a social-medicine unit in London, and a unit on climate and working efficiency at Oxford.

The cost of instituting these units and of expanding the council's other establishments, including the National

Annotations

SOME ACTIONS OF CHLORAMPHENICOL

WITH our small supplies of the new antibiotics, 'Aureomycin' and chloramphenicol, it has not been possible in this country to obtain first-hand evidence of their usefulness except in a very limited number of infections. Their activity against systemic infections with gram-negative bacteria has been demonstrated in the clinical response of typhoid fever to chloramphenicol, and the response of brucellosis to both drugs; so there was good reason for testing them against *Hæmophilus pertussis*, which is sensitive in vitro to very low concentrations of aureomycin or chloramphenicol.

In experimental infections with *H. pertussis*, aureomycin has proved effective in mice inoculated intracerebrally,[1] and chloromycetin in mice infected intranasally (so far unpublished), but very few clinical trials have been reported. Bell and his colleagues [1] have had encouraging results with aureomycin in 20 children with whooping-cough, more particularly in cases which were treated early. Payne and his co-workers [2] have given chloramphenicol in 50 severe cases in children aged 0–9 years, and found that fever, when present, disappeared on the second day of treatment and that paroxysms of coughing decreased from the third day and usually disappeared by the sixth day, leaving only a "light cough" for a few more days. They obtained good results with rectal and intravenous as well as oral administration of the drug. In this issue Dr. Gray reports good results with chloramphenicol among outpatient children whose progress was assessed from cough-counts (the number of paroxysms of coughing per 24 hours) made by the mothers. The cases were divided at the start of treatment into early or late, according to whether they were in the first or second fortnight of the infection, and alternate patients received chloramphenicol or similar capsules of milk-sugar by mouth. In both groups the treated children showed a rapid reduction in the cough-counts within 4–8 days; whooping and vomiting quickly disappeared, and the harsh hacking cough was replaced by a soft exudative cough more like that of bronchitis. In the controls, the cough-charts show, the recovery was decidedly slower. Any new claim for cure of a disease which has had so many "cures" must be received with caution, but the results with chloramphenicol certainly justify large-scale controlled trials under hospital supervision, and the Medical Research Council, through its antibiotics (non-tuberculous infections) committee, is understood to be already organising such trials in centres throughout the country. The difficulties to be overcome, besides those inherent in any controlled therapeutic trial, include the early recognition of the infection by the practitioner, the persuasion of doctor and parent that hospital treatment is often best for a young child with pertussis, and sufficient supplies of isolation accommodation and trained nurses. Gray also discussed the difficulty of giving children aged 1–3 years an intensely bitter drug like chloramphenicol by mouth. Rectal administration he found to be ineffective, and his only answer at the moment seems to be a stomach-tube; rather than agree to this, many mothers would manage somehow to get powders or capsules down, disguised in jam or syrup, or, as Payne and his colleagues found successful, in honey or orange juice. These American workers also treated 6 cases with rectal suppositories, and 5 cases with intravenous injections of a solution in propylene glycol, and these 11 children were all free of symptoms in five days or less. Gray's dosage for children, established during the trial, was 100 mg. per kg. of b weight as a loading dose, followed by three-h maintenance doses of 60 mg. up to the age of 1 y 125 mg. at 1–3 years, and 250 mg. after this age. of his patients had a short allergic reaction to her f dose, presumably because she was sensitive to s bacterial product. Perhaps the main interest in Gra paper lies in the experiments that arose out of his cl trial. He found that the older children under treatm developed a curious weakness of accommodatio print rapidly became blurred when they were readi and vision would recover temporarily after a shor rest. By weight-holding tests Gray showed that adult show a similar weakness of skeletal muscles, as well as o accommodation.

What may turn out to be an observation of far-reaching significance is that chloramphenicol kills off all the bacterial flora of the upper respiratory mucous membrane. Gray's serial nasal swabs showed that massive bacterial death, usually amounting to complete sterilisation, occurs within an hour of a single dose. The sterility continues for 3–5 days after the end of a course of the drug, and it can probably be maintained for as long as is desired by continuing or repeating the course. This finding obviously calls for further inquiry. How far does the sterilisation extend down the respirator tract? And is there any similar effect on the intestin flora?

X-RAY CINEMATOGRAPHY

GOOD angiocardiography has become essential in th diagnosis of cardiac lesions, especially in congenit heart-disease. BLE VI—USE OF SOCIAL ORGANISATIONS AFTER LEAVING

Group	Activities maintained	Activities given up	New activities joined after leaving
itution (50) ..	11 (22%)	0	10 (20%)
ool (51) ..	27 (53%)	14 (25%)	0

nual of directions has been followed, but we have parted from his scoring instructions in that we have t credited those test items which the child, because of ecial restraint or lack of opportunity, fails to perform. ll himself points out that if people in some institutional vironments are credited with such scores their total ore will be materially affected. As the object of this rvey is to compare the effects of an institutional vironment with those of a normal environment, it emed desirable to us to present a score which was free om this bias.

The social quotients were 92·9 for 50 institution chilren and 106·5 for 52 school-children. When we compared dividual items of the social maturity tests, we deduced hat the institution child is less in touch with the outside vorld than the school-child, whether by newspaper, adio, or group life; he does not get so far from home nd is more dependent on others to plan for him.

Some estimate of the degree to which institution life estricts opportunities for self-maturation can be assessed by crediting the scores of the institution child for those items which he was unable to perform "because of special restraint or lack of opportunity, but which he formerly did perform successfully when no restraints were imposed, or where the opportunity was present, or which he would perform habitually, or could quickly learn to perform if such limitations to behaviour were removed." (These are Doll's N.O. and F scores). When these items are credited the institution child's social quotient rises 4·8 points to 97·7. Thus of the difference of 13·6% between the institution quotients and the control quotients, 4·8% can be attributed to lack of opportunity.

Two examples show the extremes of general social capacity found among these children.

CASE 9.—The institution child with the lowest S.Q. (70) was an illegitimate boy of 16 who had been born in an institution, discharged with his mother to live with the maternal grandparents, and readmitted aged 2 in a state of malnutrition; he was transferred to a children's home when aged 5. He had no contacts with his family and the staff found him of wild and uncertain temper; he was regarded as "dotty" (mentally defective). Actually he had a mental age of 10·2 at the age of 16, an I.Q. of 75, and scored 34 in the matrices test (grade IV); so he was not educationally subnormal. He was educationally retarded, with a reading age of $7^1/_2$ and an arithmetic age of 7·8. He was clumsy, uncouth, his school books were appallingly dirty. Placed in a farm training school, he made no friends, had no hobbies, gave no special trouble. He had written one letter only to the matron of his old institution, could only read very simple material, played no skilled games, had no say in choosing his clothes, belonged to no group of his own age, took no interest in current events or newspapers, had never travelled any distance by himself, not even to a nearby town, had 2s. a week pocket-money but no other means. He could not look after his own health without direction. His social age was 11·2 years. The psychologist's impression at the follow-up interview was that "he might give trouble."

CASE 10.—In contrast, the institution child of the highest social capacity was an illegitimate girl, also born in an institution, and brought up in a foster home until she was 11; she had spent the last 4 years in an institution. She had frequent contact with her mother, then her only known relation, and though she had no close friends was popular with her schoolmates and in the Guides. She was a girl of superior intelligence (I.Q.129) but lost her chance for a scholarship because her foster-mother developed eccentric behaviour, and the child was transferred to an institution at the time she should have sat for her examination. At school she had been an asset in the social life, and was vice-captain when she left. In the institution the matron describes her as "the only really intelligent girl I have got, . . . trustworthy, a pleasant personality." She left the institution to live with an elderly aunt and her unmarried daughter. She wanted to be a nurse but her first employment was that of a clerk in the local Co-operative Society. She thinks of it as a dead-end job, wants to get a secretarial post, and means to attend night school and to learn shorthand and typing. Her friends were mainly from her cousin's circle, a good deal older than herself. Her mother had died in the interval between the first examination and the follow-up visit and this girl had dealt competently and efficiently with the necessary correspondence.

DISCUSSION

The outstanding feature in the social history of these institution children is the high proportion (75%) of children who are not technically orphans. More than a third (37%) of these non-orphans, however, had parents who were certified as mental defectives or of unsound mind, and nearly half (47%) had parents or sibs who were in mental hospitals or mental-deficiency colonies. None of the control group of children had insane or defective parents, and only 6 (12%) had defective sibs.

Besides the difference in domestic environment between the two groups, there is also a difference to be presumed in constitutional endowment. In our institution sample, hereditary factors are probably of considerable importance in adaptation. For example, 37% had relatives for whom evidence was available of antisocial acts. None of the control group had such relatives.

To illustrate the effect of these constitutional factors the social quotients of two groups of children have been compared. A small group of illegitimate children were excluded because there was insufficient information about one or other parent. A group of 28 children whose parents had been admitted to mental hospitals or mental-deficiency colonies, or were guilty of bigamy, desertion, or indecent assault on the children, were compared with a group of 63 children, either in institutions or brought up in their own homes, whose parents had not been admitted to mental hospitals or defective colonies and had not been recorded as guilty of antisocial conduct. The average social quotient of the first group was 91·6, and of the second 105·0. The difference of 13·6% is exactly the same as that between the average social capacity of the institution children and the school controls. That is to say, the same degree of social retardation is to be observed whether the children are grouped according to environmental circumstances (home or institution) or to constitutional factors (unsatisfactory or satisfactory parentage). Such a finding certainly weakens the case of those who argue that any social retardation is attributable exclusively to environmental influences.

In America, the concept of the "institution child" as a clinical type has been developed and elaborated. Lowrey (1940) in a study of personality distortion and early institutional care, claims that only those children admitted to institutions before the age of 2 developed a syndrome of personality distortion; this was characterised by unsocial behaviour, hostile aggression, inability to give or receive affection, inability to understand or accept limitations, and considerable insecurity in adapting to environment. Can this theory of the dangers of institutional life beginning before the age of 2 years be confirmed? Comparison of the social quotients of children admitted before and after the age of 2 years does not seem to show this age to be critical; the quotient was 93·1 for 16 children admitted under 2, and 92·8 for 34 children admitted over this age.

Goldfarb (1943) has studied the effects of institutional life in more detail, but the average I.Q. of his institution group was only 72·39 (Wechsler Bellevue) compared with 95·37 for his control group. The reported social failure of these American institution children could equally well be attributed to dull intelligence. As already the institution; 4 children had made no choice and 1 girl wept when this question was put to her. Of the girls, 6 had decided on children's nursing, 5 on hospital nursing, 4 on domestic service, and 1 on laundry work; 1 girl hoped to be a physical-training instructress, and 1 to be an actress. Many of the boys wanted to work on a farm (8); 2 specified poultry-farming, 2 dairy-farming. Engineering in some form was also popular (8), the boys specifying electrical engineering, radio-mechanic, and garage work in 6 instances. More individual choices were draughtsman, plumber, butler, and comedian.

In the school group, 3 children made no choice. Among the girls the most popular choice was factory hand (11), office clerk (6), sempstress (5), waitress (2), and shop-hand, telephonist, hairdresser, teacher (1 each). No girl chose domestic service or nursing. Among the schoolboys the choices were factory hand (4), engineer (3), vanboy (3), building trade (2), carpenter (2), and 1 each of tailor, draughtsman, painter, toolmaker, labourer, clerk, and Services. No boy in the control group was interested in farm work.

OCCUPATION

It is not to be expected that there should be a 100% correspondence between the job actually secured and the vocational choice. In the institution group 40% and in the school group 58% had this good fortune.

Even in the short time—at the most a year—since the children had left school, between the first interview and the follow-up visit, 22% of the institution group and 36% of the controls had changed their jobs. Seven (14%) of the institution children failed to adjust themselves to working conditions and returned to the institution (see table III). None of the control group failed in this way.

TABLE III—OCCUPATION DETAILS OF CHILDREN WHO RETURNED TO INSTITUTION

Child	Institution	Job chosen	Job taken	I.Q.	Time at work (months)
1	A	None	Nurse-housemaid	75	3
2	B	Children's nurse	Private service	71	11
3	C	Farm hand	Farm	84	10
4	C	Farm hand	Garden boy	65	9
5	C	Dairy hand	Garden boy	86	8
6	D	Cook	Farm trainee	72	12
7	H	Farm hand	Upholsterer	80	5

The 7 unsuccessful children came from five different homes; only one had chosen the type of job found for him. Their average intelligence was dull (I.Q.76), and their average period in work was 8 months. The following examples illustrate the type of failure:

CASE 1.—A girl who, when boarded out, was foolish with boys and inclined to drop things and smash crockery. Regarded in the home as "daft," irresponsible, inefficient, a slacker, unreliable. Did not get on with children in her first place in domestic service. Subsequently this very dull unstable girl made a successful adaptation in domestic service.

CASE 3.—This boy was described as wilfully disobedient at school, and hasty and hot-tempered. In lodgings he knocked down the landlady. He was in trouble in his second job for clumsiness; described as an "uncertain fellow."

In both groups several children said they looked forward to further promotion or to acquiring further skills; 17 (34%) institution children with an average I.Q. of 98·7, and 12 (23%) school-children with an average I.Q. of 109·9, had this ambition.

FRIENDS

It is particularly important that the institution child—who has usually been deprived of one or both parents, or comes from a disorganised family—should have the capacity and opportunity to develop personal relationships, not only with an adult, but also with children of his own age. In this survey, children were asked at the interview about their friendships, whether withi institution group or the school community, or outs Results are shown in table IV. The following is example of the friendless institution child.

CASE 8.—Both parents were mentally defective, the fa being under supervision, and the mother, known to N.S.P.C as a "bad mother," having been admitted to a defective institution when this girl was 5. The child has b in same girls' home for 9 years; the staff find her dull a retiring. She has been brought up with an older and tw younger sisters in the same institution, has visited her gra parents and been to visit her father for a weekend. Th psychologist found her of dull intelligence (I.Q.77); she wa unresponsive and unwilling to talk or to commit hersel School was "not much" liked.

TABLE IV—FRIENDSHIPS INSIDE OR OUTSIDE COMMUNIT

Group	With friends in institution	With friends at school	With friends outside	With no friend
Institution (51) ..	35 (69%)	21 (41%)	3 (6%)	3 (6%)
School (45) ..	—	36 (80%)	10 (22%)	1 (2%)

SOCIAL ACTIVITIES

Opportunities for organised social activities—f example, attendance at youth clubs, or organisations su as Scouts, Army cadets, Guides—were compared. Of t 51 institution children, 11 (22%) took part in su activities, as against 37 (79%) of 47 school controls.

Since most of the institution children made th friends within their own community, it is of interest find out how these friendships fare once the childr have left the institution. Table V gives our findin One of the friendless institution children (case 8) h already been described as of dull intelligence. Anoth 7 children were also dull, their I.Q.s ranging from 65 83, with an average of 74. Of the 8 children of avera intelligence, 2 had returned to relations and we obviously in the process of working out their position the family circle; 3 more children were placed in isolat foster-homes. Two boys are left who were well plac as far as social contacts were concerned, but who characters made personal relationships difficult.

We also compared the use made, by the two groups, organised social activities after the children had le school or institution. Results are shown in table VI.

CONTACTS WITH THE OPPOSITE SEX

Among adolescents contacts with the opposite se begin to be significant. Of 19 institution girls 2 (10% and of 27 schoolgirls 13 (48%), had boy friends or spe some of their leisure time with boys. The average I. of the girls in the institution group was 98, and of tho in the school group 99. The numbers of boys wh showed interest in girls were 4 (13%) out of 31 in th institution group (average I.Q. 87), and 5 (20%) out o 25 in the school group (average I.Q. 96). It was note that of the institution boys interested in girls, 3 we of dull intelligence.

TABLE V—FRIENDSHIPS AFTER LEAVING COMMUNITY

Group	Old friends retained	New friends made	No friends
Institution (51) ..	22 (44%)	15 (30%)	16 (32%)
School (52) ..	41 (80%)	20 (39%)	6 (12%)

GENERAL SOCIAL CAPACITY

The two groups were also assessed by Doll's (194 Vineland social maturity test. One of us has publish elsewhere his experience in the use of this test with series of several hundred children (Bodman 1946). Doll ctors a reasonable opportunity to consult and meet eir colleagues and to refresh mind and body."

he report comments on the very small number of lications to practise in the Highlands, attributing mainly to the lack of houses. Moreover, "the mittee have noted with concern that in several ances where no other suitable house was available the ring or deceased doctor's residence has been bought an intermediary before the vacancy has been filled." se transactions have been within the law.

SIZE OF LISTS

The committee do not accept the permitted maximum 4000 patients "as any proper indication of the number o can be adequately served with justice to both patient l doctor."

> "The Committee would stress that a reduction to a ower figure should be regarded as a step which must be aken (*a*) if a satisfactory standard of service is to be rovided by practitioners to the general public, and (*b*) if he medical profession is to be allowed a reasonable amount f leisure in the conduct of their lives."

The report notes a tendency by local bodies to disperse all practices when they fall vacant, or to transfer patients in these practices to doctors already on the dical list. This course, it seems, has been defended preferable to advertising a vacancy unlikely to attract ny applicants.

> "While this view may at times have certain advantages, he Committee hold that this method of disposing of prac- ices other than those of very small numbers should not e regarded as normal or desirable. They viewed with oncern the action of an Executive Council in dispersing without any allocation the patients in two practices where he combined total was over 4000."

cordingly the committee have recommended that by ulation executive councils should be denied authority disperse a practice or to transfer patients to another ctor when this seems inadvisable to the committee.

UNDERDOCTORED AREAS

The committee express the view that in the following eas the need for additional doctors appears to be ablished:

ecutive council, counties	*Area*
yll and Bute	Southend district of Kintyre
gus	Forfar
r	Dalry; Kilmarnock and Hurlford; Tarbolton, Coylton, and Drongan
mbarton	Alexandria and Renton; Dumbarton
e	Buckhaven, Methil, Leven, and East Wemyss; Cowdenbeath and Lochgelly; Dunfermline, Rosyth, Inverkeithing, and Charleston
nark	Airdrie; Bellshill
thians and Peebles	Bathgate; Musselburgh; Newtongrange and Gorebridge; Tranent
nfrew	Greenock; Johnstone; Paisley; Port Glasgow; Renfrew
rling and Clackmannan	Denny, Dunipace, and Bonnybridge; Falkirk; Grangemouth; Polmont

In the following areas, the committee believe, "addi- nal doctors would appear to be desirable":

ecutive council, counties	*Area*
r	Ardrossan, Saltcoats, and Stevenston; Kilbirnie and Glengarnock
ithness	Wick
mfries	Annan; Ecclefechan and Eaglesfield; Kirkconnel, Sanquhar, and Wanlockhead
mbarton	Clydebank
e	Kirkcaldy and Dysart
nark	Coatbridge; Hamilton; Harthill; Larkhall; Motherwell; Shotts
thians and Peebles	Bo'ness; West Calder and Addiewell; Whitburn
ss and Cromarty	Dingwall
xburgh, Berwick, and Selkirk	Galashiels
rling and Clackmannan	Alloa; Cowie, Plean, and Bannockburn; Lennoxtown
tland	Lerwick and Bressay
ty of Dundee	The area generally

The committee conclude: (1) that in general, with e exception of some districts in the Highlands, rural parts are not inadequately supplied with doctors; and (2) that some industrial parts are under-doctored. On the ground that circumstances are constantly changing, the committee are opposed to declaring any area "closed."

ELECTION CANDIDATES

In addition to those named in our last issue (p. 128) the following medical men and women are standing as parliamentary candidates.

Aberdare.—Alexander Wilson, M.A. Camb., L.M.S.S.A. (Communist).
Kingston-upon-Thames.—Nora Johns, M.B. Lond. (Lab).
London and Westminster.—J. A. Gorsky, L.M.S.S.A. (L).
Motherwell.—A. D. Robertson, M.B. Edin. (C and L).

Disabilities

44. PROLAPSED INTERVERTEBRAL DISC

I HAVE now learnt that a bad attack of sciatica may take six months or more to get well. When one of my general-practitioner friends told me this last summer I hardly believed him; and the specialists skilfully avoided giving a prognosis. Six months gives one ample time to ruminate and reflect on the many theories of causation.

Having a long back, with an extra lumbar vertebra, I always found the rugger scrum rather trying; and so are a few hours at the operating-table. My first real attack of lumbago was at the age of 25. It started during a game of squash whilst taking a difficult backhand shot: there was a feeling of something snapping in the back followed immediately by pain. A few days later I went off to winter sports with some misgiving, but the pain disappeared after the first fall. During the next fifteen to twenty years attacks of lumbago recurred—usually quite suddenly after some trivial movement, such as bending down to open a drawer or leaning over to open a car door. Once it started while I was playing a golf shot out of a bunker; but sometimes it came on several days after exercise. The pain usually subsided after a few days in bed; but there was also a chronic backache, making it difficult to bend over a bed or over a golf putt. It was impossible to do any weeding in the garden, and operating-tables had to be specially high. There was also occasional pain in the buttock, brought on by sitting for more than an hour or so.

Many treatments were tried. Manipulation, with or without anæsthesia, gave little relief. Physiotherapy in various forms—infra-red rays to the back, the "hot squat" of diathermy, or short-wave diathermy, each followed by massage—was comforting, but did not cure. (Nevertheless, I remain grateful to the many charming damsels who sweated in vain on my account.) Injections of procaine into tender nodules in the back or buttock also had little effect. Once my doctor produced a dart of pain down my leg by introducing the needle into one of these nodules. When I asked what he proposed to do next, he answered "blow it up, and break it up." He advanced with the largest syringe I have seen and "blew it up"; afterwards he applied a miniature road-drill and "broke it up." It took a week or two for the hole in the skin to heal.

The climax came when, a few days after a long weekend at golf, I rose from bed in the small hours of the morning and was quite unable to get back. I tried a frontal assault, and a rear attack, and then tried to crawl in on hands and knees—but all to no avail. My kind wife placed a mattress on the floor, and there I remained for several days till the ambulance-men arrived. The only way I could get to my feet was by making the spine rigid and being pulled up "in one piece." This was at the height of the disc season, and when the surgeon asked me to choose between several weeks in bed, followed by several months with plaster-of-paris, and an operation, I unhesitatingly chose the latter.

noted, an attempt was made in our study to match the intelligence levels in the two groups.

CONCLUSIONS

1. The children brought up in institutions were less mature socially than those in the control group, as measured by the Vineland social maturity test.

2. This relative lack of maturity is shown in fewer contacts with the community and the outside world, whether by organised social activities, the radio or press. Less advantage is taken of the opportunity to explore the neighbourhood or to travel any distance from home. Less initiative is shown in taking responsibility or in making practical plans for the future.

3. A little more than a third of the difference in maturity can be attributed to lack of opportunity and the restrictions associated with institutional life.

4. Of the institution children 30% had no contact with any relatives.

5. Less than 6% of institution children had no friends while in the institution, but over 30% were friendless after leaving the institution.

6. Before leaving, less than a quarter of institution children belonged to some kind of youth organisation compared with more than half the school group; but after leaving another 20% of the institution group joined organised social activities, while more than a quarter of the control group abandoned youth organisations.

7. Nearly 5 times as many girls in the control group, compared with the institution girls, showed an interest in boys. There was not such a marked difference among the boys: 1 institution boy in 8, and 1 schoolboy in 5, showed an interest in girls.

8. Only 40% of institution children were successful in obtaining the occupation of their choice, compared with nearly 60% of the controls.

9. Only 22% of institution children had changed their jobs, compared with over 35% of the control group.

10. Rather more than 1 in 7 institution children failed in their first job. Except for 1 boy they were all of dull, if not very dull, intelligence.

11. A greater proportion (over a third) of institution children expressed themselves as looking forward to further promotion or acquiring further skill; less than a quarter of the controls showed this ambition, which seemed to be associated with at least average intelligence.

12. A very striking discrepancy appears in the family histories of the two groups of children. Among the institution children 18% had relatives in mental hospitals, another 18% had relatives in mental-deficiency institutions, and 37% had relatives guilty of antisocial behaviour. Among the control group there were no relatives suffering from mental illness or guilty of antisocial behaviour: 11·5% of the control group had mentally defective sibs, and nearly a quarter had neurotic relatives.

13. The very high proportion of institution children with relatives of proved defect, disease, or instability of mind (72·4%) suggests that inherited constitutional factors contribute to their relative social immaturity.

14. When all the children—whether from institutions or schools—are regrouped according to the mental stability or otherwise of their parents, it is found that the differences in social maturity are exactly the same as when they are grouped according to the environment in which they have been raised. This finding suggests that constitutional factors are at least as important as environmental factors in social maturation.

We wish to thank the National Association of Mental Health, whose provisional council sponsored this investigation; and the Nuffield Provincial Hospitals Trust, who made the survey financially possible. We are also grateful to many public-assistance committees and the executive committees of various voluntary organisations for permission to examine children in their institutions, and to matrons and of homes and institutions for their coöperation. We indebted also to the Chief Education Officer of the C Bristol for providing us with facilities for the examinat a control group.

SCOTTISH MEDICAL PRACTICES COMMITTEE

First Report

WHEREAS England and Wales have an average of 730 people to the square mile, Scotland has only 170; and round the coast 160 different islands are inhabited. The difficulties of providing for a scattered and sometimes isolated population are reflected in the first report of the Scottish Medical Practices Committee which was issued last week.

MEMBERS

Since the inception of the National Health Service on July 5, 1948, 504 applications for inclusion in the medical lists of executive councils have been received. Of these applications, 148 were to establish new practices or to practise in partnership with a doctor already on a medical list; 243 were to extend an established practice into the area of an adjoining executive council; 38 were from doctors selected to fill advertised vacancies; and 75 were for limited purposes only—e.g., to serve staff of institutions.

The number providing general medical services rose from 2339 in July, 1948, to 2416 at the beginning of last December. These 2416 have undertaken to provide services as follows: (1) general medical and maternity medical services, 2006; (2) general medical services only, 315; and (3) maternity medical services only, 3. The remaining 92 are on medical lists for limited purposes.

ADMISSION TO LISTS

The report expresses concern at the length of the interval between the occurrence of a practice vacancy and the time when the final decision about filling it becomes effective, especially in cases where an appeal has been taken to the Secretary of State.

> "They [the committee] have been concerned at the inevitable hardship occasioned to their nominee, who is debarred from making any arrangements of a permanent nature until the Secretary of State has given his decision and are advised that patients tend to make other arrangements for medical care during the interim period, with the result that the practice transferable to the successor has decreased in numbers and has presumably become less attractive than when advertised."

The committee understand, however, that the present procedure may be modified.

DISTRIBUTION OF PRACTITIONERS

In surveying reports from executive councils, the committee have been impressed by the extent to which the country is served by doctors working in single-practice districts.

> ". . . this is inevitable in certain island communities, but on the mainland, and particularly in the northern counties, many practice areas are limited and confined by geographical factors—mountains or sea inlets—and the doctor in a district may be isolated from his fellows within the same Executive Council area . . . they feel that some arrangement might and should be made in order to alleviate hardships imposed by isolated conditions and to afford

In England Now

Running Commentary by Peripatetic Correspondents

NCE I have often wondered whether *I Want to be octor,* I went to Alexandra Palace to see Michael ry getting ready his television feature of that title. vas disconcerting to meet Hippocrates coming out dressing-room and Laennec going in, not to mention it appeared to be "real" medical students smoking es and wearing sports coats with patches on the ows. The studio was packed with props and scenery, l seemed in even greater confusion than usual; the naging of so much in so small a space made under-ndable the slight background noise in some of the dio shots. The scenes packed into studio A included dean's office and a very plausible imitation of the irs at the Royal College of Surgeons, complete with rtraits, bust. and banner—only they ended in nothing-ss at the first turn. Up in the producer's gallery—e "bridge" from which operations are directed—e heard mysterious incantations like "pan camera 1," nix two," "over boom." The producer-author, who mes of a medical family, took great pains to ensure curacy. A medical authority was consulted on the storical section, a car was sent to collect some real rses' uniforms, and even a humble suggestion from yself was adopted.

Nothing went wrong on the night. But I would have ked to see the face of the dissecting-room attendant hen he was asked to produce for the film sequence 1 gangrenous leg."

Some of the more lurid purveyors of what passes for ews seem to take pleasure in repeatedly telling their eaders how miserably fed we all are and how we subsist n the charity of food parcels from our more fortunate rethren overseas. It is, therefore, with great pleasure hat I record that we received the other day a heart-ending request from relatives of my wife in New Zealand o send them a food parcel. They wanted tinned fish of any kind, because they couldn't get any in New Zealand. Only too pleased to oblige, my wife managed to get several tins of herrings. She wrapped them up firmly and took the parcel down to the post office. Here she had to make a declaration of the contents, and being an honest soul she said the parcel contained herrings. Then she got a rude shock. "No unrationed foods can be sent out of the country unless accompanied by an equivalent weight of rationed foods," she was told. The parcel weighed several pounds, so this was manifestly impossible, and she sadly brought it home. I took over then and went to a different post office, where I perjured my soul but got the parcel sent off. I only hope it is not opened by the Customs at the other end. I couldn't bear to think of the herrings going 12,000 miles and then being refused admission because they hadn't brought their rations with them.

* * *

Little did we think, as we opened the innocent-looking package on that fateful January morning, that within a month one of the three of us would be a changed man, another would be on the edge of insanity, and the third would have to make a terrible decision. . . .

I am talking about the Rorschach test. We had watched its progress across Europe from Switzerland, cursed while it was held up in the London docks, and seized it eagerly when it arrived at the hospital. We thought we would practise on each other. Jamie was the first victim. He is an intellectual rather than an emotional bloke and has the naïve belief that his own actions are governed by intelligence. He had vague memories about the test but (I am convinced) secretly checked up on it before he did it. Being determined to show intellectual responses he overdid them, and turned out to be a sort of natural ENIAC, a calculating machine with no soul. This shook him. For a day or two he pondered. Then he delivered himself of the dictum: "If the test says I'm abnormal then the test's wrong"; and he has held to this point in spite of the derisive laughter of his colleagues. But now he goes about being emotional just to show that he's human after all.

George, on the other hand. is—or was—a bluff ex-Naval type whose favourite remark was "Don't worry, chaps." He evidently worked out from first principles that chiaroscuro responses showed an artistic temperament, and as he has always wanted to be artistic he got lots of them. It turned out that he had an inner conflict instead. Then he began to wonder if his responses were spontaneous after all. At first it was: "Look at me, chaps, have I got an inner conflict?" He tried vainly to discover what the conflict was, in spite of our assurances that it would be much too deep and Freudian to be unearthed by simple methods. Now he is becoming more and more solitary and introspective, and soon we shall have to take him up to the Insulin Clinic.

As for me—what am I to do? Should I pretend that I am so familiar with the Rorschach that it is pointless for me to do it? Or shall I work out a perfect personality and then produce the right answers? In either case, would they believe me?

One thing is certain: I dare not take it home. Ever since my wife did better than I did on Raven's Matrices, domestic discipline (based on the unquestionable superiority of my opinion) has gone all to pieces. After the Rorschach she would probably leave me.

* * *

Patients' newspapers provide an interesting study during the morning ward round. Before July 5, 1948, the most popular seemed to be the *Mirror*, with the *Mail*, *Express*, and *Graphic* a little behind and the *News Chronicle* and *Herald* less prominent. Very occasionally one would see the *Telegraph*. I once went round a hospital of 200 beds near midnight looking for the *Times*—ours had disappeared from the residents' room —but could not find a single copy even in the private wards. But lately things have changed. The *Mirror* still retains its popularity, but now one finds the *Telegraph* being read quite frequently, and last month two patients in the female side were taking the *Times*. Strange as it may seem, I have yet to see the *Daily Worker* in the wards; if you want that you must come into our mess, where one of the residents takes it daily.

* * *

Yesterday I experienced a new and subtle pleasure. Driving up the steep hill outside our village I passed, and passed at speed, a large expensive car with B.M.A. on its index plate. My car is old and decrepit but I have painted up the index plate so that G.M.C. shows clearly. I waved my hand as I passed and sounded a victory peal on my horn, but I fear the symbolic nature of my exploit was lost on the occupants of B.M.A.

I like having G.M.C. on my car, even though my colleagues suggest it savours of advertising: I prefer it to D.U.D., anyway. I recently saw a lot of D.U.D.s in Oxford and thought how irritating it must be to Lord Nuffield.

I am told—and I do hope it is true—that there is in Worcestershire a venereologist with a car numbered N.A.B. 606.

Chicken-skin, delicate, white,
  Painted by Carlo Vanloo,
Loves in a riot of light,
  Roses and vaporous blue.

All honour to the eighteenth-century craftsmen who, by fashioning from chicken skin such a thing of beauty and daintiness as the Pompadour's fan, inspired Austin Dobson's lines. Now we must honour no less the scientific craftsmen (*Publ. Hlth Rep., Wash.* 1949, 64, 1287) who have fashioned from chicken skin a device for feeding lice on blood and germs.

* * *

There is always an element of chance in examinations. but a friend of mine must hold the record for luck. For a "long case" in his clinical surgical examination for the Conjoint final he had a patient with syringomyelia. Three months later he took the medical part of the Conjoint final and had the same patient again. A year later he decided to complete his M.B. Lond., and, believe it or not, in clinical surgery the same case of syringomyelia was his "problem." He is to attempt the M.R.C.P. shortly and has great hopes of meeting his friend for a fourth time.

The operation, so far as I was concerned, was trivial. When it was over I was amazed that I hardly felt the incision (so different from an abdominal operation) and could lie on my back with no discomfort. There was, it is true, some pain in the calf of the unaffected leg which kept me awake at night; this was rather like toothache, and was attributed to traction on nerve-roots at the operation. But the main trouble and discomfort was from the bowels. Any acute illness, or just adopting the horizontal position, upsets the regular daily action. As there had been no action for a few days before the operation, and none for a few days afterwards, the first resembled a miniature delivery, and the pain of the resulting fissure and anal hæmatoma was far worse than any pain produced by the operation. We doctors are inclined to leave bowel regulation to the nursing staff. Believe me, from the patient's viewpoint this is a matter deserving the full attention of the physician-in-charge.

The acute lumbago was immediately relieved by the operation, and strangely enough the chronic backache also disappeared. (I have heard that often the backache is most difficult to cure.) I naturally felt rather weak after a month in bed, but was able to resume surgical work after another month, and started golf two months later. Putting was no longer painful, and the golf improved—so much so that several cups appeared on the mantelpiece.

This happy state of life continued for a couple of years; and then, during intensive training for the defence of the championship, all the symptoms recurred. Another acute attack! The lumbago once more yielded to rest in bed, and gradually disappeared. When I thought the back was well I was foolishly persuaded to enter the parents' race at the school sports, which was in the nature of a treasure hunt. While running over some rough ground I slipped in a pot-hole; and at that instant pain shot down the leg for the first time. Presumably a further prolapse. My advisers at first thought this sciatic pain might be due to rupture of an adhesion and that it would respond to a short period of bed rest. This, however, did not happen, and after a while it became clear that it was to be a severe attack. A further period of bed rest followed.

In the acute phase extension of the spine is painful, and I found it quite impossible to lie flat in bed. Lying on either side was also painful, and the only comfortable position was sitting up with the knees flexed, with a rigid back-rest supporting the pillows. One gradually gets accustomed to sleeping in this position. I got much comfort from a 'Dunlopillo' cushion placed under the thighs; but I took care to see that it did not press at the back of the knee and so obstruct the calf veins.

Flexion of the spine was also to be avoided. The tiniest forward movement was painful, and eating, washing, and shaving were quite difficult. Nor could I sit for long with the knees straight; I prayed to be quickly relieved of the bed-table, so as to bend the knees again. Bed-making was quite an ordeal. First you have to sit forward while the bed-rest is removed; then lie back while the bottom half is made; then sit forward whilst the top half is made; then turn from one side to the other while the sheet is smoothed out; then sit forward again while the bed-rest and pillows are adjusted; and finally sink back to rest. What a relief! The bedpan is also a menace. To balance on it is a feat in itself, and the pain is so excruciating that all desire to be relieved quickly passes. I was soon allowed to use a commode; and steps were taken to secure an easy action; for straining is also very painful. To move gently out of bed and use a commode seems to me much less disturbing than to use the bedpan. Absolute rest for the spine seems impossible in bed without a plaster spica; but with the help of a pulley over the bed, one can manage to move about while keeping the fairly still.

Apart from pain on movement and on coughing sneezing, there were surges of spontaneous pain. It odd that the pain got worse during sleep and could extremely severe on waking. This is probably du relaxation of muscle spasm; they say the spine actua lengthens during sleep. Pain on waking persisted several months, when other symptoms had larg disappeared; and for many weeks it was impossible sleep in any position other than the half-sitting. Ly down in bed, even with several pillows, was painf and so was lying on either side. Lateral flexion of spine is said by some to be free; but in my case it st produces pain now several months after the attack. other words, the only comfortable position is with t spine kept rigid in the degree of flexion or extensi permitted by the ailment. The pain was at tim very severe, but it was almost always relieved by ta codein. co.

After four weeks' bed rest a plaster jacket was applie At this stage no attempt was made to overcome t kyphosis; the lumbar curve returned of its own acco during the succeeding weeks. Apart from rather seve discomfort around the ribs for the first twenty-four hou the plaster jacket was no great encumbrance; but plaster made no immediate difference to the pain. T periods of freedom were probably longer, but if plaster got into the wrong position the pain was actua worse; it was essential to sit on a rubber cushion, that the bottom edge was clear of pressure.

The plaster was rather hot, but when I got back work it did not stop me operating; of course in sum heat it might have been unbearable. The plaster very skilfully applied; in fact it was so snug that, a five or six weeks, rectal bleeding started and œde and petechial hæmorrhages developed around ankles. Because of these symptoms, which apparen are an uncommon complication, the plaster was repla by a belt which I wore for several months.

Slowly the pain in the thigh diminished, then pain in the calf, and finally that in the foot. It wa long time before I was free of pain on waking, and was a month or two before the bed-rest could be dispen with or I could sleep on my side. Pain on coughing sneezing varied from day to day, and it was less pain to cough with the knees flexed. In contrast, hyperexte sion of the head, as in drinking, or rotation of the nec as when tightening a tie, would produce immediate pa in the leg. Sitting with legs outstretched—the equival of straight-leg raising—was possible only for sh periods. Thus to be left too long with the bed-ta was an ordeal, and a bath was equally trying. Washi my own back was impossible; and it was a nuisance to be able to put on my own socks and shoes, or to my toenails—which can never be done so well by any else, except a trained chiropodist. Even now, picki something off the floor is possible only by bending knees or kneeling on the floor, and is better left to othe Sitting in a low chair, as in the driving seat of a c requires extensive hip flexion which in turn flexes the lov lumbar spine and sacrum and produces pain; so I ha to be content with back-seat driving. Unless the car large, getting in and out is also difficult. For mont the calf muscles were tender, and painful cramp cou easily be brought on by stretching them.

It is not always easy to explain how each and eve pain is produced, but it becomes quite clear how imp tant is the spine in most bodily movements. A b cannot immobilise the last few lumbar vertebræ co pletely, but it limits the movement of the spine as whole and thereby acts as a reminder and a check activity. It is also a great comfort and should be ke handy to relieve any threatened attack.

n they are present alone—i.e., when they have been hed.

he "curdling" effect is due not so much to an ration of the blood as to a change in the myanesin, if red cells are present the pigment released by ir breakdown may to some extent be adsorbed.

t is fallacious to argue, as Dr. Davison is inclined to that because he has injected myanesin without effect, it is safe. One *can* inject air into a vein without toward effects. Is air therefore safe? We too have ected myanesin without apparent harm, but neverthe- s we still feel that there is a potential danger and that care should be observed.

We were interested in Dr. Berger's comments. Having d no experience of myanesin given by the oral or ramuscular routes, we do not feel able to give an inion on these methods. However, it is obvious that e intravenous method has dangers which seriously nit the usefulness of the drug, as Dr. Berger has nfirmed.

Dr. Berger's view that the concentration in the blood the effective factor in causing the hæmolysis appears be correct. When we stated that our impression was at serious hæmolysis was more likely to occur with rger doses of myanesin, we based this on a standard ilution of the drug (10%), given at a standard rate ml. in 6 sec.), the only variable being the total amount dministered.

Essex County Hospital,
Colchester.

JOHN B. PENFOLD.

THE FIRST MEDICAL EXAMINATION

SIR,—I have one point that I would like to make in nswer to Dr. Johnson's letter of Jan. 21. There is o doubt that the same standard is maintained for the xternal and internal examinations for London first .B. The equating of the standards for the two examiations is ensured by the fact that the same external xaminers, who are teachers of other universities, act or both examinations; and it is one of their duties to ee that the standard of the papers and of the marking s equivalent. Furthermore, some internal students whose colleges do not hold special college examinations ake the same papers as the externals and are examined y the same examiners; yet the pass percentage of these andidates is always markedly higher than that of the xternals.

London, W.1.

C. C. HENTSCHEL.

PRIMARY UMBILICAL SEPSIS IN THE ADULT

SIR,—The article of Jan. 7 by Mr. Greig and Mr. Shucksmith prompts me to record the following case.

On May 22, 1949, a man, aged 45, was admitted to hospital complaining of soreness and discharge from the umbilicus of seven days' duration. On the previous day he had developed nausea, attacks of shivering, and severe pain in the epigastrium and on the right side of the abdomen. Six months previously he had been treated for chronic bronchitis.

On admission, the patient looked ill; his temperature was 100·2°F, and pulse-rate 85 per min. Examination revealed a slight purulent discharge from the umbilicus, which admitted a probe to a depth of 3 cm. There was tenderness and guarding in the epigastrium and to the right of the umbilicus. An ill-defined mass, dull to percussion, was palpated extending from the subcostal margin to the umbilicus. The patient was not jaundiced. Only the right testicle was present in the scrotum.

The white blood-cell count was 16,000 per c.mm. (polymorphs 84%); urinary diastatic index 29 units. Straight X-ray examination: abdomen, nothing abnormal; chest, old fibrosis at the right apex.

In view of the uncertain diagnosis, laparotomy was performed, on May 24. On opening the abdomen through a right paraumbilical paramedian incision the liver was seen to be smooth, and enlarged to the level of the umbilicus. There was no free fluid in the peritoneal cavity. The anterior abdominal wall in the vicinity of the umbilicus, the falciform ligament, and the ligamentum teres were acutely inflamed and œdematous. The greater omentum had become adherent to these structures and showed some fibrinous exudate. The other abdominal viscera were normal. The left testis could not be demonstrated. A piece of omentum was taken for biopsy and the abdomen was closed.

From the biopsy specimen the omentum was reported to be œdematous and congested with well-marked signs of acute-on-chronic inflammation.

Convalescence was uneventful. When seen recently, the patient looked fit and well. The liver had diminished in size but was still palpable below the subcostal margin.

Further investigation showed that the plasma-proteins, the serum alkaline-phosphatase, the thymol-turbidity and flocculation tests, and the serum-bilirubin were normal.

It would seem that in this case the inflammatory process originated in the umbilicus and spread along the ligamentum teres. Despite the gross enlargement of the liver, no interference with hepatic function was demonstrated by the usual tests.

St. James' Hospital, London, S.W.12.

J. BURKE.

FILARIA AND LOEFFLER'S SYNDROME

SIR,—Transient pulmonary infiltrations have been noted by many workers throughout the world. Loeffler[1] described such changes which were demonstrable by X rays and were accompanied by eosinophilia. This association was also described by Weingarten,[2] who called it tropical eosinophilia. Loeffler believed the condition was an allergic pulmonary reaction to various antigens. Soysa and Jayawardena[3] found mites in the sputum of 11 out of 30 cases of this syndrome, and Van der Sar[4] found pulmonary acariasis in his 2 cases.

I have observed filariasis associated with Loeffler's syndrome in at least 4 cases. In all of them microfilariæ were found in the peripheral blood, radiography showed that the lungs were affected, and blood-counts showed leucocytosis and eosinophilia. In 3 of them there were asthmatic attacks, and in 3 cases eosinophils were found in the sputum. Fever is a fairly common accompaniment of filariasis; it does not respond to sulphonamides or to penicillin, which fact suggests that it is not due to secondary bacterial infection.

CASE 1.—In June, 1946, a man aged 23, who lived in a filarious district, had a rigor followed by intermittent fever, for which he was admitted to hospital, where no malaria parasites were found in his blood. He had well-marked eosinophilia. His fever did not respond to quinine, and he left hospital after eight days. As soon as he left hospital his temperature came down and remained normal until December, 1946. He then started complaining of heaviness in his right leg, and in a week typical elephantiasis of his right leg developed, which was successfully operated on in September, 1947.

I saw him first in December, 1947, when he was complaining of asthma and fever. He had eosinophilia (eosinophils 60%), and his sputum contained many eosinophils. Actively motile microfilariæ were found in his peripheral blood. Radiograms of his chest over three weeks showed fleeting pneumonic infiltrations, most marked near the lung roots.

CASE 2.—A girl, aged 13, became ill in February, 1947, with cough, expectoration, and wheezing. She was admitted in May, 1948, for the third time to King George's Hospital, Lucknow, where active microfilariæ were found in her peripheral blood. She had scattered rhonchi throughout her lungs. Her sputum contained eosinophils, and her white-cell count was 12,000 per c.mm. with eosinophils 60%. Radiography of the lungs showed soft shadows, which cleared in three weeks.

CASE 3.—A boy, aged 6 years, was brought to King George's Hospital, Lucknow, in May, 1947, with a history of wheezing since the previous October. He had a slight cough with mucoid sputum, most of which he swallowed. Apart from rhonchi in the lungs, he appeared healthy. His white-cell

Letters to the Editor

FERTILITY AND FAMILY PLANNING

SIR,—Your annotation of Jan. 14 quotes the recent report on fertility[1] as stating that 40% of women seeking advice for *sterility have no treatment ordered.*

In my own clinic I find that a large number of patients do not come from medical practitioners at all; they come from other sources including various welfare centres, and as a result of articles which have appeared in such papers as *Picture Post, Home Chat,* and *Housewife.* The women have written to the Editor, who has referred them to such bodies as the Marriage Guidance Council and the Family Planning Association, which in turn refer them to the nearest subfertility clinic. All these women give the same story of having sought advice and been told that nothing could be done, when in fact a great deal could have been done for them. For example, a case of sterility lasting ten years was treated with a variety of hormones but had never had a vaginal examination by her doctor; and she had seven fibroids. In another case the wife had been subjected to many operative procedures: in fact, her husband had azoöspermia.

This report provides evidence that we should give wider publicity to the existence of sterility clinics—through the medical press to doctors, and through the medium of the B.B.C. and popular feature articles to the general public. The popular magazine on health which the British Medical Association is to publish might well take up this issue.

M.O., SUBFERTILITY CLINIC.

ACUTE DIVERTICULITIS OF THE CÆCUM

SIR,—I read Mr. Shaw's article last week with great interest. I was reminded of a case with which I had to deal last July, and which illustrates some of the dangers that Mr. Shaw brings to notice.

A man, aged 64, was admitted to the Clayton Hospital, Wakefield, under the care of Mr. Lawson Light, with a history that three days previously he had noticed the onset of mild colicky pain in the epigastrium, which later had become more severe and which, after about twenty-four hours, had become localised to the right iliac fossa. There had been no vomiting; bowel actions had been normal; and there was no previous history of intestinal disorder.

On examination he was found to be a healthy man, with slight fever and a furred tongue. There was tenderness and guarding in the right iliac fossa. On rectal examination nothing abnormal was found. The history suggested a straightforward acute appendicitis and preoperatively this diagnosis was confidently made.

The peritoneal cavity was opened through a McBurney incision and a normal appendix found. There was, however, a small mass, about the size of a walnut, on the posterolateral wall of the cæcum, at its junction with the ascending colon. This mass was hard on palpation and the surrounding cæcum was œdematous. The omentum had migrated to the mass and was partially enveloping it. Several enlarged mesenteric lymph-nodes were to be felt. The remaining portions of large bowel were normal. The liver was normal and there was no peritoneal effusion. It was decided that the condition was early carcinoma of the cæcum. The McBurney incision was converted into a Rutherford Morison one and a right hemicolectomy performed. The immediate postoperative period was most satisfactory and the patient got up on the second day.

The pathologist reported that sections taken from the mass in the wall of the cæcum showed only an inflammatory reaction, there being no evidence of malignancy. There were no other diverticulæ in the resected portion of gut.

The patient's convalescence proceeded well until the seventh day, when he died within fifteen minutes from a massive pulmonary embolism, which was confirmed at autopsy, when examination of the remaining portion of large gut showed no abnormality.

I should like to make one comment on a poin by Mr. Shaw. He suggests that the correct tr for this condition is diverticulectomy; and he de how he clamped the base of the diverticulum as i an appendicectomy, ligating the stump and then bur it. In the case I have described, such a proc would have been quite impossible and it would been necessary to remove a portion of the cæcal wal

ASHLEY A. ROB

HÆMOLYTIC EFFECTS OF MYANESIN

SIR,—Dr. Armstrong Davison, in your Dec. 10 i seems to find the word "overwhelming" for the evid that 'Myanesin' produces intravascular hæmo incorrect, and apparently wishes to substitute the "strong." He is not supported by Dr. Berger i letter of Jan. 14. Dr. Davison then proceeds to dem his own contention of strong evidence by trying to that myanesin does not produce hæmolysis at all, that the brown coloration we obtained was du breakdown products of the myanesin.

We agree with Dr. Davison that spectroscopic evid is important, but so far as we remember this exan *tion has only been carried* out by one person,[1] then with negative results. Before accepting it we sh like to see it confirmed. This is the only experim evidence against hæmolysis.

On the other hand we have shown that hæmo occurs with "curdling" in vitro,[2] and if Dr. Da cares to mix a little myanesin and blood, and wat under the microscope, he can see with his own eyes red cells breaking up. Since this is a very rapid pr we see no reason why it should not also occur in vein. At the same time we should like to point that no brown pigment is produced when plasm serum is mixed with myanesin. It appears only red cells are present, and it will appear with t

THE SMALLER HOSPITAL

r,—May I endorse very strongly the plea for the ition of small hospitals in crowded areas, which was forward by you towards the end of last year ?[1]

write as a social worker for many years in an area h depended greatly on the Waterloo Hospital for nen and Children. The smallness of the hospital was efinite asset; a few yards from the entrance the ous mother would be at the door of the clinic.

. Thomas's and Guy's are justly beloved and are erred by many; but the range of large buildings, the passages, the numerous clinics, even the unending ession of hurrying students, nurses, and porters can ly stupify an anxious woman and frighten a nervous d.

do not hesitate to affirm that hundreds of women in thwark and North Lambeth have lost a feeling of urity through the closing of the Waterloo, and that fears of many nervous children will be increased in ir new hospital by the absence of immediate personal ognition and of the almost homely atmosphere which y knew at the Waterloo.

ondon, W.1. HELEN BARLOW.

INFLUENCE OF HEART-RATE ON CARDIAC OUTPUT

SIR,—From his letter of Jan. 14, it appears that ofessor McMichael knows enough about me to allege at "I lack experience of modern laboratory work." erhaps he has overlooked my criticism[2] of the modern" laboratory work on cardiac output and also the Haldane method of blood-gas analysis.

About the failure of the ferricyanide method, the late r Joseph Barcroft was in full agreement with me when discussed this question with him in 1923 at the International Congress of Physiology. Subsequently, so far I know, Sir Joseph published no investigation based n this method. I worked out a new and, I believe, perior method for blood-gas analysis based on entirely w principles.[3] Does Professor McMichael really think at it is a special achievement of modern technique use a "water-immersed gas-analysis apparatus"? his was in use about a hundred years ago by Bunsen-eppert, and it was used by me with the Haldane pparatus forty years ago. I think that he must have en referring to some really novel device which he left nmentioned.

Regarding my criticism of the determination of xygen consumption by the spirometric method, the nipping apparatus is the most elaborate and most opular; yet even with this device the errors due to uncer-ain temperature distribution, and therefore uncertain ater-vapour tension, together with observational istakes, produce an error in the result of up to ±10%.

Professor McMichael reproaches me for my "imagin-g" that the "cardiac catheter is a coiled spring" because him it is "flexible and imposes no mechanical obstacle" the contraction of the heart. If he placed a catheter his mouth, he would know better what disturbance of nction may result in an even more sensitive cavity ach as an auricle or ventricle of the heart.

Taking a further point from Professor McMichael's etter, I will admit for a moment that modern investiga-ion has corrected my figure (1909) for average cardiac utput from 4 litres to 5 litres per minute; though n fact I did discuss "the possible range in health and isease" at that time. However, I fail to see what this as to do with the reported variation of the minute-olume between 2 and 12 litres for different individuals nder similar experimental conditions.[4] It seems to me that such large variations are a severe condemnation of the experimental method.

Lastly, I must contest the paragraph in which Professor McMichael refers to Mackenzie and Thomas Lewis as if their school of thought had been confined to this country. Their teaching was known and respected all over the world; and so was their observation "that the reduction of ventricular rate by digitalis in auricular fibrillation was of major importance in the production of clinical improvement." I am convinced that in establishing this empirical result these able cardiologists did not confuse two such elementary ideas as the power of the heart and the performance of the heart, as Professor McMichael and his school have done.

London, W.1. J. PLESCH.

SIR,—Despite Professor McMichael's reply to Dr. Plesch's criticisms of the article by Kelly and Bayliss, it seems to me that some factual information is lacking. Kelly and Bayliss, though they report many of their actual observations of the heart-rate and of the venous pressure, give only their deductions on the cardiac output in the form of calculations from the Fick formula.

Those interested would like details of the changes in the denominator and numerator of the equation. Does the oxygen consumption go up, and if so, by an amount which can be recorded comfortably on a spirometer? While the Douglas and Courtice modification of the Haldane blood-gas analysis apparatus is excellent for determination of blood gases with a normal amount of dissolved oxygen, surely this method would not show all of the *sevenfold increase* in dissolved oxygen which will be present during the examination if the spirometer contains 100% oxygen.

If it is deduced that the pulmonary blood-flow is increased only because of diminished arteriovenous difference, then is this because the mixed venous oxygen saturation has increased; or does the arterial saturation also increase, but to a smaller extent?

These facts, and a note on the experimental errors which the authors found with apparatus used in their laboratories, would allow readers to form a serious judgment of the results.

FRACTURES AND DISLOCATIONS IN GENERAL PRACTICE

SIR,—We are grateful for your review (Dec. 24) of the 2nd edition of this book, but we feel we must comment on the inaccuracies contained in the last sentence.

This states that "there is no mention of the invaluable Capener nail for trochanteric fractures" (of the femur) and continues, "the ritual of reduction and plaster is still advised for vertebral fractures." In the third paragraph of p. 192 of the book it is stated that a special type of nail and plate may be required in the treatment of pertrochanteric fractures of the femur. It is true that the Capener nail is not specifically recommended, but this nail is only one of many similar patterns and we do not agree that it is "invaluable." It is true also that "the ritual of plaster is still advised for vertebral fractures." Your review implies that this method of treatment should not have been advised. Recent work by Nicoll, and the experience of us all, has shown that good results can be obtained in some of these fractures without the use of a plaster-jacket; nevertheless in the majority of cases, under the most usual circumstances, the "ritual" of reduction and plaster is still the accepted treatment and this method has not been abandoned by surgeons of experience and sound judgment.

count was 18,300 per c.mm. (eosinophils 40%). There were no eosinophils in the sputum, and no tubercle bacilli were found in the sputum or on gastric lavage. Actively motile microfilariæ were found in his peripheral blood. No abnormality was found on radiography of the lungs. The Wassermann reaction was positive, but a Kahn test was negative.

This case is interesting in view of Neumann's statement[5] that microfilariæ are usually not found before the seventh year after infection, and the claim of Dickson et al.[6] to have found microfilariæ in 1·6% of 244 children under the age of 5 years.

Case 4.—A man, aged 25, was admitted to the Railway Hospital, Jubbulpore, on Sept. 5, 1948, with a history of two months' chyluria, three weeks' asthmatic attacks, and a week's irregular febrile episodes. There were scattered rhonchi and a few crepitations in his lungs. His white-cell count was 10,000 per c.mm. (eosinophils 70%). Actively motile microfilariæ were so numerous in his peripheral blood and so constantly present that slides made at any time of the day or night were full of them. The sputum contained eosinophils but no acid-fast bacilli. Radioscopy showed diffuse mottling of the lung parenchyma. The patient was treated with 'Neostibosan.' The asthma and the radioscopic appearances cleared.

My thanks are due to Dr. B. B. Bhatia, dean of the University of Lucknow, for permission to publish cases 2 and 3; Dr. S. N. Lahiri, chief medical officer of the Great Indian Peninsula Railway, for permission to publish case 4; and Dr. L. J. Hiwale, pathologist, Railway Hospital, Jubbulpore, for help in laboratory work.

CEREBRAL PALSY

Sir,—We were interested by Professor Illingworth's letter,[7] with much of which we agree. We touched on most of the points he raises and would have dealt with them more fully had we not desired to make our article[8] short enough to arouse interest.

We realise, of course, that the differentiation between cerebral palsy and mental retardation is difficult, and we stated that in these cases diagnosis is not easy. Professor Illingworth states that it is incorrect to say that retarded infants smile early. We agree: what we said was that they smile easily. Regarding the sitting position, manipulative behaviour, dribbling, sucking, and so on, we tried to make it clear that the mentally retarded child may show deficiencies here, but that in the cerebral-palsied child the difficulty is due to a damaged motor system, whereas in a mentally retarded child the disability is due to generally retarded development. A major object of our article was to direct attention to the fact that even in slight cases the disorder is one of the whole motor system rather than a defect of the limbs. In over four hundred cases seen in the past two years there has been not one of monoplegia.

With reference to the letter from Dr. Asher and Miss Schonell,[9] we were emphasising that cerebral palsy is usually not diagnosed until the child is at least two years old, whereas signs are present before that age and treatment in infancy produces better results. We have had cases under twelve months, and in most of our other cases the histories show that symptoms were present at an early age. It is true that, when questioned, many mothers will say that the child was noted to be backward in some way at six months or so; but on closer questioning they will not infrequently explain that the baby was "stiff" or "limp" or unable to balance the head, or that the thumb remained in the palm. As to the intelligence of spastics and athetoids, our child
so young that we cannot assess them by th
methods and we rely on previous history,
observation, and response to treatment.

Dr. Gerrard's letter[10] on kernicterus raises
important point, and he has obviously been
follow his cases much longer, and has seen more
type of case, than we have. As we said in our
our experience of this particular type is very limi

MYSTERIOUS MARRIAGE

IR,—I have no wish to defend either myself or my nt book, *Mysterious Marriage*, against the criticism our review; but deeper issues are at stake than what call my whimsicalities.

'he review says: "exactness is the one thing which Howe nowhere approaches. . . . The fairies at the tom of the garden whom Jung invited . . . have long stayed their welcome."

n some horror and amazement, Sir, I ask whether u would have us all put such imponderables as love l faith, poetry and imagination, myth and dream, o exactly fitting, pseudoscientific, psychological ait jackets? I would rather keep the fairies at the ttom of my garden.

I believe that the fanatical followers of Freud have come a menace, as they suffer from obsessional neurosis thout knowing it. I said as much in *Mysterious Marriage*, it would not expect a Freudian reviewer to agree with me.

London, W.1. E. GRAHAM HOWE.

INFLUENZA COSMO

SIR,—I was much interested in Sir Henry Bashford's escription last week of a new influenzal syndrome, s I have been a victim of a very similar condition for he last ten years. The changeover from the "normal" old-complex, with which I had been familiar all my life, o the cold-plus-delayed-tracheitis complex, which has egularly recurred since the winter of 1939–40, was udden, dramatic, and infuriating. The tendency to profane and obscene language, which Sir Henry describes, s strong. I must disagree, however, with his description of the effects on smoking. All taste for a pipe disappears during the initial cold, but returns just when the dry tickling cough is at its worst. The resulting paroxysms incline me to call the syndrome, in honour of its discoverer, "Bashford's blasphemous bronchitis.'

Beaconsfield, Bucks. MICHAEL REILLY.

ARMY MEDICINE IN THE LATE WAR

SIR,—This series of articles by Dr. Todd was written, intentionally perhaps, in a dogmatic and provocative style calculated to produce dissent, if not resentment, in the minds of many, especially of those with experience as senior military officers. It is to be hoped, however, that this will not obscure the many sound views put forward; it may even be hoped that some of these will receive attention from higher authority.

I am particularly in sympathy with Dr. Todd's protest at the manner in which medical boards were induced to extract from the *Nomenclature of Diseases* some label which would serve to "invalid" from the Forces a person who was useless and inefficient as a soldier. I agree that these persons should be discharged as inefficient—not as invalids who can pose as heroes, broken in health as the result of their war service.

Croydon. T. W. PRESTON.

SIR,—May I reply to some of the adverse criticism of my article?

Dr. de Burca (Dec. 31) says: "Clinical diagnosis must have been easy for him if all his cases showed fever every second or third day, but why he should have waited this time to make a diagnosis I do not understand." All my cases did not, of course, reveal such fever, and I did not say that they did. So far from advocating waiting to make the diagnosis, I said that "regimental M.O.s should have been given instructions that whenever a soldier seemed to have malaria, the exhibition of anti-malaria remedies should commence immediately." His statement that a blood-slide would *invariably* give the diagnosis within thirty minutes is astonishing, since I have never heard it doubted, even by the most enthusiastic advocates of microscopy, that in some cases of malaria it is impossible in the early stages to find the parasite in the peripheral blood. Dr. de Burca finally says: "His account of the ease with which civilians dealt with malaria is ludicrous. I have known of deaths from M.T. infections among European civilians. . . ." I did not suggest that malaria in civilians is never fatal. or that it never causes serious illness. What I did say was that civilians began taking quinine as soon as they thought that they had malaria, and that if their attacks were mild they carried on with their ordinary life either immediately or the next day. Numerous civilians with whom I have spoken have certainly said this was their method.

Dr. Dimson (Dec. 31) and Dr. Crosby (Jan. 14) both defend the regulations about malaria and other conditions on the ground that they were intended for M.O.s who were very ignorant of tropical diseases. This ignorance no doubt did justify the making of regulations, and I was not condemning them in general but in particular. A regulation urging regimental M.O.s to begin anti-malaria treatment as soon as they suspected malaria would, I believe, have been excellent. Dr. Crosby says: "Failure to submit cases of malaria in particular to the full therapeutic course meant an enormous loss of man-power by subsequent relapse and subhealth; and for this reason, if for no other, insistence was placed on the official régime." I never suggested that malaria cases should not have "the full therapeutic course." My objection was to the practice of keeping all soldiers in hospital for the whole duration of the course. Dr. Dimson says that if I had had my way "bacillary dysentery would have been treated with emetine." Since bacillary dysentery is nearly always an acute self-limited disease of short duration, and I was advocating treating with anti-amœbic drugs those giving a history going back for weeks or months of recurrent diarrhœa, abdominal discomfort and dyspepsia, and the other symptoms of low-grade amœbiasis (even though the entamœba could not be isolated), I am unable to understand this statement.

May I say finally on the general subject of diagnosis by isolating the organisms of disease that I did not suggest—neither did I intend to imply—that it is always a waste of time to look for the organism. On the contrary, the positive finding of an isolated organism is often most valuable, and at times virtually conclusive. It is the negative finding ("no organism found") which usually proves nothing. As regards tuberculosis, syphilis. subacute infective endocarditis, kala-azar and many other diseases, moreover, this view is universally accepted. But in the case of malaria and amœbiasis (when cysts are discovered) even the positive finding is far from conclusive, since the organisms which cause them are frequently harboured by those who are well, though vegetative *Entamœba histolytica* is perhaps always evidence of active disease.

Dr. Keatinge (Jan. 14) cannot understand why I should object to medical examinations in industry while admitting that they have some value for soldiers. My explanation for this differentiation is that, whereas it seems reasonable to exclude a man from the Army who is unduly liable to fall sick, it is wrong to exclude him from an industrial job. For if there are reasons for excluding him from this job, frequently there are equally good reasons for excluding him from any other, with the result that through no fault of his own he remains unemployed or does blind-alley occupations.

Dr. Gordon Smith and Dr. Guymer (Jan. 21) say that I imply there should be no inquiry and investigation into various septic conditions affecting persons whom

MALE-TOAD TEST FOR PREGNANCY

SIR,—I summarise here the results of 116 pregnancy tests made on the Ceylon toad *Bufo melanostictus*, which Badhuri and Bardhan lately reported[1] as being susceptible to chorionic gonadotropin.

In contradistinction to the experience of Haines[2] with *B. arenarium*, I found that the injection of acid urine caused a considerable mortality in the early experiments, the toad dying within an hour. Acid urines were therefore neutralised with sodium carbonate and filtered before injection into the toad's dorsal lymph-sac. Positive results can generally be obtained in $1^{1}/_{2}$ hours. It is not necessary to collect the urine with a pipette, since handling of the toad generally causes spontaneous voiding of urine, which can be collected on a glass slide placed against the cloaca. If a negative result is obtained, more urine is collected from the toad up to 5 hours (in controls in this series up to 21 hours).

The results of the 116 tests were as follows :

	No. of tests	*Positive*	*Negative*
Known pregnancy—			
In first 5 mos. of pregnancy ..	41	39	2
In last 3 " " " ..	19	16	3
Doubtful pregnancy—			
(Amenorrhœa for 1–20 weeks) ..	19	..	19
Complete abortion—			
Proved	5	1	4
Doubtful	2	..	2
Hydatidiform mole after evacuation ..	4	2	2
Controls—			
Male	12	..	12
Female	14	..	14

The 2 negative results obtained in the first 5 months of known pregnancies were both in cases of abnormal pregnancy : one of the women had had pyelitis for 5 months, and the other hyperemesis for 2 months. The earliest positive result was obtained on the fifth day after the first missed period. There were no false negatives in 8 cases of amenorrhœa of less than a month's duration. The presence of pregnancy in the very early positive cases was confirmed by their later histories.

The later histories of the 19 women in whom pregnancy was doubtful were as follows :

Had periods subsequently	6
Negative Friedman test	3
Probably menopausal (aged 45–50)	3
Amenorrhœa over three months, no enlargement of uterus	4
Amenorrhœa less than three months, no clinical confirmation of pregnancy	3

The histories of the last three cases are as follows :

CASE 1.—Five previous abortions. Last regular menstrual period from July 9 to Aug. 1, bleeding one day. Tested negative on Sept. 26.

CASE 2.—Childbirth June 20. Breast-feeding continues. Uterus not enlarged, as felt per vaginam. Tested negative on Sept. 26.

CASE 3.—Last regular menstrual period on June 19. Uterus felt per vaginam to be retroverted, not enlarged. Tested negative on Aug. 31.

Confirmatory Friedman tests, which would have proved valuable, could not be done, owing to a dearth of suitable rabbits.

Of the 5 proved complete abortions 2 were negative a day before the fœtus was expelled. Similar observations are reported by Haines.[2] The case giving a positive result was negative 7 days later, and abortion took place on the 9th day. The 2 other cases were tested after the abortion. Further work is necessary to determine whether the test would be of prognostic value in cases of threatened abortion. In these cases negative results would probably be more significant positive ones.

The test was read with ease in every case. N positives were obtained. The toads did not lose sensitivity at any time during the period of obser Positive results were obtained with as little as l of urine. The results with *B. melanostictus* have so encouraging that this test is taking the place Friedman test in our institute.

Medical Research Institute,
Colombo.

L. G. JAYEWARDI

RISKS OF ANTI-HISTAMINE MEDICATIO

SIR,—I agree with Dr. J. Stanley White (Ja in his statement that histamine is no antidote in of poisoning by "antihistaminics." The drugs widely used as anti-histamines are not physiol antagonists of histamine, as adrenaline *is*; they blocking agents and prevent in some way the hista from reaching the receptors of effector cells.

Contradicting himself, Dr. White states that "in people, notably asthmatics, even *though* they saturated with an anti-histamine, it is possible injections of histamine would produce severe reacti This appears to me to be incorrect. On the con experimental and clinical experience shows clearl the effect of histamine in asthmatic as well as in subjects can be weakened or prohibited by thera doses of potent anti-histamine drugs. The effect inhalation of histamine aerosol, for instance, can be prevented or cut short, even in asthmatic su by drugs.[1]

Helsingborg, Sweden.

PAUL KA

POSTOPERATIVE PARALYSIS IN THE UP EXTREMITY

SIR,—In your issue of Jan. 21 Mr. Ewing and Dr. do great service in drawing attention to the inc incidence of the above condition and its possible re to the muscular flaccidity associated with the curare as an adjunct to anæsthesia.

The mechanism in gall-bladder operations is somewhat obscure, but stretching of the brachial by over-abduction of the arm and pronation of the arm can readily be demonstrated during any ope for radical removal of the breast. After the hu insertion of the pectoralis-major muscle has been se the humerus loses much of its protection against exc abduction and external rotation. When the ax glands have been removed it is easy to demonstrat mechanism described by Mr. Ewing—over-abductio external rotation bringing the head of the humeru in the axilla and stretching the vascular bundle tog with its partial investment, the brachial plexus.

I have three cases on record where such cond actually obliterated the radial pulse ; and in t these, a blood-transfusion simultaneously ceased t In each case adduction towards the patient's side *a* *lifting the arm-board at its free end* restored the puls allowed the transfusion to recommence.

King's College Hospital,
London, S.E.5.

A. H. GALL

SIR,—In a number of the cases described by E and Kiloh, it appears that the arm position respo had been chosen to facilitate repeated intrav injections by the anæsthetist. This factor can be nated if the anæsthetist uses, instead, one of the ext jugular veins. By slight finger pressure just abov middle of the clavicle, this vein can, with a little pra nearly always be distended and made readily piercea

The safe position of the arms described by Dr. (elbows by the side of the chest, forearms flexed a

Obituary

NORMAN PATTERSON

M.B. EDIN., F.R.C.S.

. Norman Patterson, consulting surgeon to the throat ear department of the London Hospital, died at his e at Ashridge Park on Jan. 16, at the age of 72.

on of the Rev. James Patterson, of Ancrum, he went his father's Border manse to Edinburgh. where attended Melville College and later the university. ce he held the Grierson bursary and was later awarded senior medal in anatomy. After qualifying in 1900 he came to London to continue his studies at King's College and at the London Hospital where he was appointed demonstrator in anatomy.

Of that period in his life Sir Arthur Keith writes: "Norman Patterson and I came together in the early years of this century at the London Hospital, where I was senior demonstrator of anatomy and he a junior one. A demonstratorship in years gone by had been a stepping-off place for ambitious Londoners who aimed at becoming full members of the hospital staff. Roxburgh, Sequeira, Harold Barnard, and Hugh Rigby had ade the passage safely. But then they were Londoners, hile Norman was from Edinburgh. Nevertheless he ade the passage; he was appointed to the staff as sistant surgeon in the ear department. He made his ay, not by any display of mental brilliancy but by s patent honesty of word and thought, and his genius r making and keeping friends. After his marriage the eith and Patterson households enjoyed many happy ocial evenings together; these times seem now very emote. One had to know Norman for a long time efore his special gifts were discovered. His powers as painter in oils impressed me."

Patterson was also on the staff at Golden Square, he Central London Ophthalmic Hospital, and the lorence Nightingale Hospital, and he was consultant o the Royal School for the Deaf and Dumb at Margate. He contributed the chapters on his specialty to Choyce's *ystem of Surgery* and to Walton's *Textbook of Surgery*. One of his most recent papers was the description in our columns in 1944 of a radical external operation for hronic sinusitis, in which he was particularly interested. By that time his love of the country had already drawn him away from London, and he had finally settled at Ashridge Park, where he spent more and more time in his garden, and competed successfully with professionals n the design and construction of modern beehives. He came to believe strongly in the emigration of specialists rom London, and during the late war this home served as a convenient base for his work in the E.M.S. After the war was over not only did he continue as an active consultant laryngologist and aurist to the Royal Bucks Hospital, Aylesbury, but for the past few years he had also worked regularly at the Mid-Herts Hospital at St. Albans; indeed he made his last tour of duty there only two days before his death. All the theatre staff liked to work for him: as one of the sisters put it. "there was never any panic or flap in the theatre even among the most junior nurses; he was always most courteous and fatherly towards them."

Writing of earlier days at the London, a former house-surgeon makes the same point: "He was an admirable chief—conscientious, quiet, courteous. To serve as his house-surgeon was not dramatic or very exciting but was a most useful and very pleasant experience. He retained the tradition of formal hospitality to his students and housemen, and many will have a delightful memory of dinners in Portland Place and of helping with the bog garden near Reigate in which his primulas flourished so famously." Many others, who did not know him as an artist in gardens, recognised him as an artist with the paintbrush or with the trout-rod. He had a full, interesting and valuable life, and will long be gladly remembered.

Mr. Patterson married Miss Winnie Crockford, who survives him with their daughter. Their only son was killed on active service in Greece in 1944.

WALTER SYDNEY LAZARUS-BARLOW

M.D. CAMB., F.R.C.P.

Prof. W. S. Lazarus-Barlow, who formerly held the chair of experimental pathology in the University of London, and was director of the cancer research laboratories at Middlesex Hospital, died at Bexhill on Jan. 15 at the age of 84.

His family tree was interesting, for his father, John Barett Lazarus, traced his descent to Moses Maimonides, physician to Saladin, while his mother, Martha Barlow, traced hers to Sarah Trimmer, founder of sunday schools and the friend of Dr. Johnson. He took the name of Lazarus-Barlow on his 21st birthday. From the City of London School he went to Downing College, Cambridge, where he was a scholar and prizeman, graduating B.A. in 1887. After continuing his medical studies at St. George's Hospital he took his M.B. in 1889, proceeding to the M.D. in 1894. At St. George's Hospital he had acted as demonstrator of morbid anatomy and curator of the museum, and later he became pathologist and lecturer on pathology at Westminster Hospital. In 1901 he was elected F.R.C.P. At the end of the same year he nearly lost his life from blood-poisoning following a thumb-prick during a necropsy. His left arm had to be amputated, but special messengers were sent to the Pasteur Institute in Paris for the new antistreptococcal serum. He was the first patient to receive the treatment in this country, and he himself always believed that it tipped the scales in his favour.

Lazarus-Barlow did not allow this handicap to interrupt his career. In 1910 he became director of the cancer research laboratories at Middlesex Hospital, two years later he became lecturer in pathology, and in 1920 he was appointed to the new chair of experimental pathology. A member of the grand council of the British Empire Cancer Campaign, he was also a member of the cancer committee of the Ministry of Health. S. R. writes: "He was one of the first pathologists in this country to carry on experiments designed to obtain fundamental knowledge about the effects of X rays and radium upon living cells and especially living cancer cells. Hector Colwell, Cecil Mottram, and Helen Chambers, among others, were inspired by his work, for Lazarus-Barlow was a man of ideas with an extensive knowledge of pathology. He was also a skilled experimentalist and his colleagues were often amazed at the way in which he accomplished with one hand what they could with difficulty achieve with two. It is nearly 40 years ago that, by strictly quantitative methods using a Rutherford emanation electroscope, he showed the presence of radium in normal and in cancer tissues. Turning his attention to radiotherapeutics he showed, by an ingenious experiment on the rectum of the rat, that two different varieties of cells responded quite differently to the same dose of radium irradiation according to whether the dose was administered in a long or a short time. Carcinogenesis has now become a big subject, and here again Lazarus-Barlow was early in the field in his very nearly successful attempt to produce carcinoma, by inserting in the gall-bladder of the rabbit small gall-stones in the middle of which was sealed a small quantity of radium. His research work at the Cancer Research Laboratories at Middlesex Hospital had a definite radiological aspect for many years, and this was continued on his retirement. A man of great capabilities and great industry, he retained an abiding faith in his fellow men."

His *Manual of General Pathology* first appeared in 1898 and his *Elements of Pathological Anatomy and Histology for Students* in 1903. In 1909 he chose as the subject of his Croonian lectures to the Royal College of Physicians radioactivity and carcinoma. As departmental editor of the 14th edition of the *Encyclopædia Britannica* he wrote many of the articles, including the monograph on cancer research.

Outside his work, his family, his home, and his garden occupied his life to the exclusion of all else. In an address it is proposed to employ in the preparation and handling of food. As I said that, when a candidate for a job is a potential danger to others, there may be the strongest grounds against appointing him, I cannot see any justification for their statement. I am nevertheless grateful to them for pointing out that I did not mention the special case of food-handlers. They also say that "no industrial medical officer is able . . . to *forbid* any prospective employee taking a job. His function is purely advisory to executive management . . ." But if managements accept the advice of the medical officer, as I presume they usually do, whatever the theoretical position he in fact is responsible for men being refused employment.

Farnham, Surrey.

J. W. TODD.

EPILEPSY AND ORGANIC DISEASE

SIR,—I should like to thank Prof. Nattrass for his courteous reply last week to my letter. I am glad that we agree about the importance of frequent re-examination of patients with epilepsy.

With regard to the suggestion that I only quoted his figures partially, I gave his post-mortem results in full. I purposely omitted those cases diagnosed clinically for two reasons: (1) a clinical diagnosis is partly a matter of judgment, and in some cases, no matter how expert one may be, one is later proved to have been wrong; and (2) I do not think that three years is a sufficiently long period of observation to exclude cerebral tumour. In Tooth's series of 500 cases, adult astrocytomas were found to have been present for periods varying from 67 to 89 months.[1] I think that it is more accurate to go by the results of findings at operation and post-mortem examination when these are available.

H. W. DALTON.

Public Health

Births and Deaths in England and Wales

THE following rates for births and deaths in 1949 are announced by the Registrar-General in his weekly return for the week ended Jan. 14 (rates for the fourth quarter only in parentheses): live births 16·7 (15·4) per 1000 total population; stillbirths 22·6 (22·5) per 1000 total live and still births; deaths 11·7 (11·6) per 1000 total population; and deaths of infants under one year 32 (32) per 1000 related live births.

Animal Health

The report for the years 1938–47 from the Animal Health Division of the Ministry of Agriculture[2] deals first with foot-and-mouth disease. This is the most important remaining epizootic; and the soundness of the slaughter policy—without which the disease would become endemic—is shown very clearly by the figures. Since 1942, when over 27,000 cattle were slaughtered, only 1000–5000 cattle have been slaughtered annually; over the same period 3000–13,000 sheep and pigs were slaughtered each year. Losses through swine-fever numbered 106,954 in 1940, but only 824 in 1947. The number of cattle slaughtered under the Tuberculosis Order dropped from nearly 20,000 in 1938 to 6545 in 1947; and this undoubtedly reflects a real decline in the number of cows with advanced tuberculosis. Each year about a quarter of a million calves and maiden heifers are vaccinated against contagious abortion—a procedure which has reduced very effectively the incidence of the disease. Rather strangely, isolated outbreaks of infection with *Brucella melitensis* took place during the period under review. The section of the report dealing with contagious abortion and bovine mastitis recalls that quarters can be freed of infection with *Streptococcus agalactiæ* by one or two injections up the teat canal of 50,000–100,000 units of penicillin.

Medicine and the Law

Claim of Official Privilege

Squadron Sergeant-Major J. E. Pettitt, ag
sent from the 5th Battalion, Royal Tank Re
Germany to undergo, with others, a special d
at the Guards' depot at Caterham. It was a
course for men not used to drilling. He colla
dropped dead.

At the inquest the pathologist who had made a
gave evidence that the dead man (6 ft. 3 in. i
had a heart twice the normal size, high blood-
and diseased arteries; to go through a strenuou
in that physical condition was "the worst thing
have done." Another non-commissioned office
to the same course, told the coroner that he
had a thorough medical examination by his ow
doctor before being sent.

The coroner asked what examination had been
of the deceased. An officer produced Army form
as the medical certificate which Pettitt had br
with him. The coroner pointed out that this certi
said no more than that the man was free from infe
disease and was going on a course; it gave no inf
tion about his fitness. Asked for the medical-hi
sheet of the dead man, the officer said that the
commandant had a ruling from the War Office tha
was a privileged document and could not be discl
The coroner, adjourning the inquest for a fortnig
order that the doctor who issued the certificat
Germany could appear and give evidence, observed
if the War Office declined to produce the medical-his
sheet, they could not object if unfavourable infere
were drawn. During the adjournment, he added,
War Office might consider waiving the official privi
if it existed; he would have thought they would h
wished to help the inquiry by producing this import
document.

Births, Marriages, and Deaths

BIRTHS

BRADY.—On Jan. 15, at Colchester, the wife of Dr. T. J. Brady—a son.

CANT.—On Jan. 11, in Trinidad, the wife of Dr. F. E. V. Cant—a son.

CHISHOLM.—On Jan. 16, the wife of Dr. John Chisholm—a son.

HOWAT.—On Jan. 17, to Dr. Margaret Howat (née Harker), wife of Dr. James Howat—a son.

LINDAHL.—On Jan. 11, in London, the wife of Mr. J. W. S. Lindahl, F.R.C.S.—a daughter.

LAYBOURNE.—On Jan. 8, in London, the wife of Dr. M. N. Laybourne—a daughter.

NICHOLL.—On Jan. 18, the wife of Dr. Patrick Nicholl—a son.

OWEN.—On Jan. 17, at Harrow, the wife of Mr. E. N. Owen, F.R.C.S.—a son.

WALKER.—On Jan. 15, at Southend-on-Sea, the wife of Dr. J. Walker—a son.

MARRIAGES

DURRANS—GOULDING.—On Jan. 11, at Wolton-under-Edg
Glos, John Faraday Durrans, M.R.C.S., to Gwendoline Ma
Goulding, S.R.N.

JACOBSON—HARVEY.—On Jan. 17, in London, Bernard Jacobso
M.B., to Moyra Harvey.

DEATHS

BOND.—On Jan. 14, at Ewell, Surrey, Charles Shaw Bond, B.A., M.B. Camb., D.P.H., aged 80.

CAMPBELL.—On Jan. 17, at Dundee, Henry Gordon Campbell, L.R.C.P.E.

FALK.—On Jan. 18, at Sanderstead, Herman Falk, M.B. Camb., D.P.H., D.T.M. & H., major, I.M.S. retd.

HORNIBROOK.—On Jan. 20, at Gerrards Cross, William Henry Hornibrook, F.R.C.S.I., D.P.H., aged 81.

LAZARUS-BARLOW.—On Jan. 15, at Bexhill, Walter Sydney Lazarus-Barlow, B.A., M.D. Camb., F.R.C.P., aged 84.

MARTIN.—On Jan. 11, in London, Charles Gutherless Martin, B.A. Camb., M.R.C.S.

MORT.—On Jan. 19, in Manchester, James Henry Mort, B.A. Camb., M.R.C.S., aged 78.

PATTERSON.—On Jan. 16, at Ashridge Park, Herts, Norman
Patterson, M.B. Edin., F.R.C.S.

SWEENEY.—On Jan. 16, in London, Edward Reginald Stanisla
Sweeney, M.R.C.S.

TAYLOR.—On Jan. 18, at Wareham, Ernest Charles Taylor, B.A., M.B. Camb., major, I.M.S. retd, aged 71.

an investiture at St. Bartholomew's Hospital on Jan. 20 ollowing doctors received insignia of the order:

mmander: Dr. A. P. Spark.

icers: Dr. E. P. Scott and Dr. D. M. Macmanus (nominated rsonal esquires by Lord Webb-Johnson); Mr. F. W. Law, el T. J. L. Thompson, Major Albert Ehrmann, Dr. J. A. E. M. ey, Lady Wakeley.

ociation of Surgeons of Great Britain and Ireland

ne annual meeting of the association will be held in don on Thursday, Friday, and Saturday, May 4, 5, and 6. re will be discussions on Gravitational Ulcers of the Leg ner, Prof. M. Boyd), the Gastric Blood-vessels (Prof. H. Bentley), Anticoagulants in Surgery (Prof. R. M. es, Toronto), and the Alimentary Physiology after Surgical atment for Simple Peptic Ulcer (Prof. Charles Wells).

rveian Society of London

t the annual general meeting of the society on Jan. 18, a sentation was made to Sir Cecil Wakeley on his retirement n the office of honorary treasurer. The retiring president, Desmond MacManus, gave an address on General Practice the Last 30 Years, and Dr. R. R. Trail was inducted as sident for 1950.

nterian Society

The annual dinner of the society will be held at Grosvenor use, Park Lane, London, W.1, on Thursday, Feb. 16, 7.30 P.M. Tickets (25*s.*) may be had from Dr. Franklin knell, 14, Wimpole Street, W.1.

yal Institute of Philosophy

Today, Friday, Jan. 27, Mr. Karl Britton will give the first four weekly lectures on the Philosophy of Human Nature. the lectures will be given at 5.15 P.M. at 14, Gordon Square, don, W.C.1.

yal Society

On Thursday, Feb. 16, at 2.15 P.M., Prof. J. H. Burn, F.R.S., l open a discussion on the Mode of Action of Local Hormones. On Thursday, March 16, at 11 A.M., Prof. S. Zucker-n, F.R.S., will open a discussion on the Measurement of owth and Form. Both meetings will be held at Burlington use, Piccadilly, London, W.1.

nference on Fertility

A conference on fertility, which it is proposed will be the ugural meeting of a new Society for the Study of Comrative Fertility, will be held at the house of the Zoological ciety of London on June 16 and 17. Further particulars y be had from Dr. G. I. M. Swyer, Obstetric Hospital, iversity College Hospital, Huntley Street, London, W.C.1.

.H.O. Meeting

At the opening of the fifth session of the executive board the World Health Organisation, in Geneva on Jan. 16, Arcot Mudaliar (India), the chairman, expressed the hope t the governments of the Soviet Union, the Ukraine, elorussia, and Bulgaria would reconsider their decision to thdraw from the Organisation. Previously Dr. Melville ackenzie (U.K.) had suggested that any further attempt sway these countries from their decision "would not be the interest of the Organisation." The chairman said that the Organisation difficulties had arisen because 17·85% the budget for 1948 and 26·71% of the budget for 1949 e still outstanding. He also announced that a European alth conference is to open on March 6, when the question establishing a regional office for Europe will be examined.

International Conference on Tuberculosis and Diseases of the Chest

At a meeting of the British Tuberculosis Association on Jan. 20, Dr. Stephen Hall announced that a Conference on Tuberculosis and Diseases of the Chest will be held in September, 1951, in connexion with the Festival of Britain.

Anderson-Berry Prize

A David Anderson-Berry medal, together with a sum of money amounting to about £100, will be awarded this year by the Royal Society of Edinburgh for work on the therapeutic effect of X rays on human diseases. Applications, which may be based on published or unpublished work, should reach the general secretary of the society, 22, George Street, Edinburgh, 2, not later than March 31.

Symposium on Chloramphenicol in Milan

The Italian Centre of Studies on Antibiotics is holding an international meeting on the properties and use of chloramphenicol, with special regard to typhoid fever and brucellosis, in Milan during the Italian Congress on Antibiotics which takes place from June 3 to 5. Further information may be had from the centre, Via Francesco Sforza 38, Milan.

Treacher Collins Prize Essay

The subject for the next award of this prize (£100) is Exophthalmos in Relation to Endocrine Disorder. Essays should be submitted to the hon. secretary, Ophthalmological Society of the United Kingdom, 45, Lincoln's Inn Fields, London, W.C.2, before Sept. 30, 1951.

British Council

Sir Henry Dale, O.M., has been elected president of the council in succession to Lord Riverdale, who has resigned. Sir Henry was a member of the executive committee from 1943 to 1949, and chairman of the science advisory committee from 1942 to 1949.

London Lock Hospital

At a meeting on Jan. 9, the North West Metropolitan regional hospital board considered a letter from the Ministry of Health concerning the board's proposal for the future user of the Lock Hospital. The board agreed that, while it "had no alternative other than to accept the Minister's decision that the proposed change of user should not be proceeded with, a reply be sent reiterating the board's views on the matter."

Remuneration of Hospital Employees

The Ministry of Health has asked hospital authorities to assist in carrying out the national policy on the stabilisation of personal incomes in a number of ways, including the following:

1. Where a wage or salary has been nationally determined, there should be no departure from it except in the case of staff who have protected personal rates because they are transferred officers who have elected to remain on their previous rates, or because they are covered by a no-detriment provision in the national agreement.
2. Where there is no nationally determined rate of pay, present occupants should continue to be paid in accordance with their present wage, salary, or salary-scale; and no increase should be made without reference to the Ministry.
3. Where posts fall vacant for which there is no nationally determined rate, the matter should be referred to the Ministry.
4. Where the grading of posts is a matter for boards or committees to settle within the framework of a national agreement, alterations in existing gradings should not be made unless there is either a substantial change in duties or a serious anomaly which must be corrected without delay.

Joint Advisory Committee in Otolaryngology

This committee has been set up by the following bodies: British Association of Otolaryngologists (Mr. Myles Formby), British Medical Association (Mr. E. D. D. Davis), British Postgraduate Medical Federation (Prof. F. C. Ormerod), Institute of Laryngology and Otology (Mr. C. Gill-Carey), Royal College of Surgeons of England (Mr. V. E. Negus). Professor Ormerod has been elected chairman and Mr. John H. Young honorary secretary. The objects of the committee are to consider and coördinate the facilities for postgraduate students of otolaryngology in London and the Provinces, and to give advice about posts as house-surgeons and registrars for otolaryngological departments or hospitals. An advisory bureau for postgraduate students is to be set up at the Institute of Laryngology and Otology, 330, Gray's Inn Road, London, W.C.1 (TERminus 4311). The postgraduate bureau at the Royal College of Surgeons of England is also available for inquiries.

on Playthings to a small local society he once said that the best playthings for parents were children, and for children, parents. He certainly lived up to this maxim. In 1907 he bought a small cottage in Essex called Smith's Hall, standing in two acres of rough meadow full of thistle which was the original home of that Squire Pudney, mentioned in Baring-Gould's *Mehalah*, who grew more thistles than wheat. But the rough ground was gradually tamed and turned into a beautiful garden which was the pride of his heart, till increasing years and the difficulty of getting help forced him to sell it in 1941. For many of his last years he did the *Times* crossword puzzle every day, and this he still managed even when small retinal hæmorrhages forced him to use a magnifying-glass. His brain remained alert and clear, and the day before he died he was talking happily to his son, Dr. Percy Lazarus-Barlow, on all sorts of medical topics, both recent and old.

OTTO RIESSER

M.D.

Dr. Otto Riesser, formerly professor of pharmacology in the universities of Greifswald and Breslau, died in Frankfort-on-Main on Dec. 1, aged 67. A pupil of Jaffé, Ellinger, and Embden, his main interest was the pharmacology and physiological chemistry of the muscle, and he published many valuable papers on creatine. During the Hitler régime he found refuge in Holland, but he returned to Germany in 1945. When the German Pharmacological Society was refounded in 1948, he was elected its first president. His death will be a loss to his colleagues and pupils, who valued his great friendliness and his criticisms, which were always stimulating and encouraging.

DR. A. G. GIBSON

F. G. H. writes: "From his earliest years, Gibson was a passionate naturalist, a keen and accurate observer, with a particular devotion to wild birds and wild flowers, and in his later years an expert and proficient gardener. To this pastime he gave his few leisure hours during the burden of overwork, inevitable in the years of the late war. The spirit and functions of the naturalist and the physician have so much in common that this happy combination has often been found in distinguished members of the medical profession.

"Gibson's appointment to the Radcliffe Infirmary staff in 1911 coincided with the appointment of Sir William Osler as regius professor of medicine, and between these two men there formed bonds of friendship, admiration, and affection, which were abundantly evident in their happy professional collaboration, and in their combined influence upon the reputation and standing of the hospital, and upon the general standard of medical work in the region served by the hospital. A sound pathologist provides the leaven without which no hospital staff can achieve excellence, however distinguished may be the ingredients provided by the clinicians; and Gibson was a sound pathologist, of the generation sometimes labelled clinical pathologist. As a clinician his whole outlook was based upon a sound pathology, and he played an important part in the formation and development of two major societies. An original member of the Association of Physicians, he was for many years an editor of the *Quarterly Journal of Medicine*. In 1922 he was in the chair at the first committee meeting to consider the possibility of forming the Cardiac Club, which was later enlarged to become the British Cardiac Society. To each of these societies he gave valuable service both as an officer and contributor.

"His contributions to the Oxford school of medicine were outstanding. To many generations of medical colleagues and students the sturdy courage which enabled him to master and subdue a lifelong shyness, and to give of his best where the duties of his office required, will be an unforgettable memory. Patient, understanding, kindly, and courageous, he possessed in a unique degree that *aequanimitas* which his friend Osler prescribed as a desirable characteristic of a good physician. Both of his sons have followed their father's profession."

Notes and News

ECONOMY IN PRESCRIBING

The following letter, signed by Sir Wilson Jam
chief medical officer of the Ministry of Health, is be
to medical practitioners:

"Recent investigations have shown that large
money are being spent on drugs and medicines of
value or on unnecessarily expensive brands of standa
prescribed in the National Health Service. The Cen
Scottish Health Service Councils therefore set up a
joint committee which consisted of members suggest
among others, the three Royal Colleges, the Scottish
Corporations, the British Medical Association, the
Pharmacopœia Commission and the Society of Apoth
On the recommendation of this Committee, the
Council has advised the Minister to send a letter to all
asking for their coöperation in the prevention of
prescribing.

"The Committee considered that much unnecessa
was due to the prescribing of proprietary brands—parti
those which are widely advertised—instead of standard

every six months. The annual cost of the complet
is two guineas; and the cards published in 1949
obtained by new subscribers for an additional guinea
should be sent to the Pharmaceutical Journal (N
Bedford Place, London, W.C.1.

University of London

On Monday, Feb. 27, at 5.30 P.M., at the London
Hygiene, Keppel Street, W.C.1, Prof. J. W. Bigger,
on Synergism and Antagonism in relation to Anti
Substances.

University of Birmingham

On Dec. 16 the following degrees were conferred:

Ch.M.—J. N. Wilson.

M.B., Ch.B.—Joyce Bott, D. W. Davis, D. A. Gale, P.
C. C. Griffiths, K. A. G. Guy, R. S. T. Hoy, Pauline M.
I. E. J. McLauchlan, Brian MacMahon, E. T. Mathews,
Medcalf, Jeanne C. Poppitt, L. E. Tyler, Ruth A. Watson,
Wilkins, E. W. Witherspoon.

rsity of Glasgow

Jan 14 the following degrees were conferred:

—Thomas Cochrane, David Douglas, J. D. Dow, R. M.
B. R. Hillis, Margaret H. Kelsall, A. A. Kirkland, J. C. W.
lane.
I.—D. H. Clark.

Smith, James Steel, Harry Steingold, Sarah F. Stevenson,
Sturrock, W. M. Walker, J. R. Welsh, W. D. Wilson.

r of St. John

an investiture at St. Bartholomew's Hospital on Jan. 20 llowing doctors received insignia of the order:

nmander: Dr. A. P. Spark.
ers: Dr. E. P. Scott and Dr. D. M. Macmanus (nominated sonal esquires by Lord Webb-Johnson); Mr. F. W. Law, el T. J. L. Thompson, Major Albert Ehrmann, Dr. J. A. E. M. y, Lady Wakeley.

ciation of Surgeons of Great Britain and Ireland

e annual meeting of the association will be held in lon on Thursday, Friday, and Saturday, May 4, 5, and 6. e will be discussions on Gravitational Ulcers of the Leg ner, Prof. M. Boyd), the Gastric Blood-vessels (Prof. H. Bentley), Anticoagulants in Surgery (Prof. R. M. es, Toronto), and the Alimentary Physiology after Surgical atment for Simple Peptic Ulcer (Prof. Charles Wells).

rveian Society of London

t the annual general meeting of the society on Jan. 18, a sentation was made to Sir Cecil Wakeley on his retirement n the office of honorary treasurer. The retiring president, Desmond MacManus, gave an address on General Practice the Last 30 Years, and Dr. R. R. Trail was inducted as sident for 1950.

nterian Society

The annual dinner of the society will be held at Grosvenor use, Park Lane, London, W.1, on Thursday, Feb. 16, 7.30 P.M. Tickets (25*s.*) may be had from Dr. Franklin knell, 14, Wimpole Street, W.1.

yal Institute of Philosophy

Today, Friday, Jan. 27, Mr. Karl Britton will give the first four weekly lectures on the Philosophy of Human Nature. the lectures will be given at 5.15 P.M. at 14, Gordon Square, ndon, W.C.1.

yal Society

On Thursday, Feb. 16, at 2.15 P.M., Prof. J. H. Burn, F.R.S., l open a discussion on the Mode of Action of Local Hornes. On Thursday, March 16, at 11 A.M., Prof. S. Zuckern, F.R.S., will open a discussion on the Measurement of wth and Form. Both meetings will be held at Burlington use, Piccadilly, London, W.1.

nference on Fertility

A conference on fertility, which it is proposed will be the ugural meeting of a new Society for the Study of Comrative Fertility, will be held at the house of the Zoological ciety of London on June 16 and 17. Further particulars y be had from Dr. G. I. M. Swyer, Obstetric Hospital, iversity College Hospital, Huntley Street, London, W.C.1.

.H.O. Meeting

At the opening of the fifth session of the executive board the World Health Organisation, in Geneva on Jan. 16, Arcot Mudaliar (India), the chairman, expressed the hope at the governments of the Soviet Union, the Ukraine, elorussia, and Bulgaria would reconsider their decision to thdraw from the Organisation. Previously Dr. Melville ackenzie (U.K.) had suggested that any further attempt sway these countries from their decision "would not be the interest of the Organisation." The chairman said that the Organisation difficulties had arisen because 17·85% the budget for 1948 and 26·71% of the budget for 1949 e still outstanding. He also announced that a European alth conference is to open on March 6, when the question establishing a regional office for Europe will be examined.

International Conference on Tuberculosis and Diseases of the Chest

At a meeting of the British Tuberculosis Association on Jan. 20, Dr. Stephen Hall announced that a Conference on Tuberculosis and Diseases of the Chest will be held in September, 1951, in connexion with the Festival of Britain.

Anderson-Berry Prize

A David Anderson-Berry medal, together with a sum of money amounting to about £100, will be awarded this year by the Royal Society of Edinburgh for work on the therapeutic effect of X rays on human diseases. Applications, which may be based on published or unpublished work, should reach the general secretary of the society, 22, George Street, Edinburgh, 2, not later than March 31.

Symposium on Chloramphenicol in Milan

The Italian Centre of Studies on Antibiotics is holding an international meeting on the properties and use of chloramphenicol, with special regard to typhoid fever and brucellosis, in Milan during the Italian Congress on Antibiotics which takes place from June 3 to 5. Further information may be had from the centre, Via Francesco Sforza 38, Milan.

Treacher Collins Prize Essay

The subject for the next award of this prize (£100) is Exophthalmos in Relation to Endocrine Disorder. Essays should be submitted to the hon. secretary, Ophthalmological Society of the United Kingdom, 45, Lincoln's Inn Fields, London, W.C.2, before Sept. 30, 1951.

British Council

Sir Henry Dale, O.M., has been elected president of the council in succession to Lord Riverdale, who has resigned. Sir Henry was a member of the executive committee from 1943 to 1949, and chairman of the science advisory committee from 1942 to 1949.

London Lock Hospital

At a meeting on Jan. 9, the North West Metropolitan regional hospital board considered a letter from the Ministry of Health concerning the board's proposal for the future user of the Lock Hospital. The board agreed that, while it "had no alternative other than to accept the Minister's decision that the proposed change of user should not be proceeded with, a reply be sent reiterating the board's views on the matter."

Remuneration of Hospital Employees

The Ministry of Health has asked hospital authorities to assist in carrying out the national policy on the stabilisation of personal incomes in a number of ways, including the following:

1. Where a wage or salary has been nationally determined, there should be no departure from it except in the case of staff who have protected personal rates because they are transferred officers who have elected to remain on their previous rates, or because they are covered by a no-detriment provision in the national agreement.
2. Where there is no nationally determined rate of pay, present occupants should continue to be paid in accordance with their present wage, salary, or salary-scale; and no increase should be made without reference to the Ministry.
3. Where posts fall vacant for which there is no nationally determined rate, the matter should be referred to the Ministry.
4 Where the grading of posts is a matter for boards or committees to settle within the framework of a national agreement, alterations in existing gradings should not be made unless there is either a substantial change in duties or a serious anomaly which must be corrected without delay.

Joint Advisory Committee in Otolaryngology

This committee has been set up by the following bodies: British Association of Otolaryngologists (Mr. Myles Formby), British Medical Association (Mr. E. D. D. Davis), British Postgraduate Medical Federation (Prof. F. C. Ormerod), Institute of Laryngology and Otology (Mr. C. Gill-Carey), Royal College of Surgeons of England (Mr. V. E. Negus). Professor Ormerod has been elected chairman and Mr. John H. Young honorary secretary. The objects of the committee are to consider and coördinate the facilities for postgraduate students of otolaryngology in London and the Provinces, and to give advice about posts as house-surgeons and registrars for otolaryngological departments or hospitals. An advisory bureau for postgraduate students is to be set up at the Institute of Laryngology and Otology, 330, Gray's Inn Road, London, W.C.1 (TERminus 4311). The postgraduate bureau at the Royal College of Surgeons of England is also available for inquiries.

Royal Medical Foundation of Epsom College

Applications are invited from women doctors or the wives or daughters of doctors for two vacant pensions from the Margaret and Josephine Hurd-Wood Gift Fund. Forms of application are available from the secretary's office, Epsom College, Surrey.

Royal Sanitary Institute

The institute will hold its Health Congress this year at Eastbourne from April 24 to 28.

The 1951 Congress will be held in Southport from April 23 to 27.

Pictures by Mental Patients

An exhibition of psychopathological art is to be held at the International Congress of Psychiatry in Paris from Sept. 18 to 27, 1950. Those who wish to show exhibits are asked to write to Dr. E. Cunningham Dax, Netherne Hospital, Coulsdon, Surrey, before the end of February.

Medicine Bottles

The Ministry of Health is sending to pharmacists copies of a humorous poster urging patients to return their medicine bottles. Since the campaign to secure the return of bottles was launched last September, the proportion returned has varied in different parts from 1% to 50% of those issued.

Course on Rheumatic Diseases

A weekend course on the chronic rheumatic diseases, with lectures, ward rounds, and practical demonstrations, is being held at the rheumatism unit of St. Stephen's Hospital, Fulham Road, London, S.W.10, on March 25 and 26. Prof. G. W. Pickering will open the course with a discussion on the Significance of the Effect of 'Compound E' in Rheumatoid Arthritis. Other speakers will include Dr. Francis Bach, Dr. Grace Batten, Dr. E. G. L. Bywaters, Dr. Colin Edwards, Dr. Philip Ellman, Mr. A. Timbrell-Fisher, Mr. H. E. Harding, Dr. David Shaw, and Dr. A. G. Signy. Further information from the medical registrar at the unit, or from the Fellowship of Postgraduate Medicine, 1, Wimpole Street, W.1.

British Railways Appointment

Dr. G. O. Hughes has been appointed medical officer Euston in the London Midland region.

Dr. Hughes was educated at Swansea Grammar School and Liverpool University, where he graduated M.B. in 1938. After holding an appointment as resident surgical officer at Macclesfield General Infirmary he joined the R.A.M.C., and with the rank of major he served in the Western Desert, Sicily, Italy (where he won the Military Cross), Middle East, Madagascar, and Germany. On his return to civilian life Dr. Hughes joined the Southern Railway in 1947 as medical officer, and he has held the post of divisional medical officer, Southern region, London Bridge.

Refresher Courses in Tuberculosis

The N.A.P.T. hopes to hold a course for doctors at Davos from March 25 to April 2. Courses for doctors, school nurses, health visitors, administrators, and social workers are to be held at St. Thomas's Hospital, London, S.E.1, on April 18, 19, and 20, on tuberculosis in children and the use of B.C.G. Three-day clinical courses are being continued at Cheshire Joint Sanatorium, Market Drayton, Salop, and at King George V Sanatorium, Godalming, Surrey. Dates for the first six months of 1950 are as follows:

Cheshire Joint Sanatorium: Feb. 8–10; March 8–10; April 12–14; May 10–12.
King George V Sanatorium, Godalming: Feb. 21–23; May 10–12.

Further information may be had from the secretary of the Tuberculosis Educational Institute, Tavistock House North, Tavistock Square, W.C.1.

The openings in the various branches of the Colonial Service have been described in an official publication, *Appointments in His Majesty's Colonial Service* (H.M. Stationery Office. Pp. 111. 1s.).

The 1949–50 edition of *Winter on the Sussex Coast*, a symposium on the various resorts, has been published, price 1s., by the Crabtree Press Ltd., 57, Tivoli Crescent, Brighton. Doctors who apply will receive a copy gratis.

The first volume of *Clementson's List of Scholarships, Fellowships, and Grants to Students and Research Workers*, which is now ready, contains a medical and dental section. It may be had from 2, Post Office Terrace, Cambridge (price 21s.).

Diary of the Week

JAN. 29 TO FEB. 4

Tuesday, 31st

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. I. Muende: Histopathology of the Skin.

THE IRON AND STEEL INDUSTRY

CATHERINE SWANSTON
M.R.C.S., D.P.H., D.I.H.
the Department of Public Health and Social Medicine, University of Edinburgh

E Iron and Steel Act, which received the Royal t on Nov. 24, 1949, provides for the nationalisation eel-making plants with an annual output of 20,000 or more. To have nationalised all plants making and steel would have involved not only the iron and industry but also the firms which engage in these esses as part of their normal manufacturing trade. s, many engineering works maintain their own iron dry, and to put all such foundries under public ership would seriously embarrass the metal and neering trade. The new Act ensures that none of e ancillary departments will be affected, but that the n output of the industry will in future be a State onsibility. It seems pertinent at such a time to vey the special features of the different processes hin the industry and the health hazards to which the rkers in these processes are exposed.

ORIGINS OF THE INDUSTRY

The smelting of iron to fashion weapons and domestic d agricultural implements is one of the oldest industries, de widespread by the ubiquity of iron-ore deposits, ich are found in every part of the globe. Great itain is not particularly rich in these deposits, but deposits she possesses have been mined for centuries, d the smelting of iron ore was one of the country's liest industries. At first charcoal was used as fuel, d since it was easier to transport the ore than the fuel, elting works were set up in the forest area of the ssex and Kentish Weald and the Forest of Dean, d for centuries these remained the iron-manufacturing stricts. In Scotland there remain to this day traces the old smelting works in the Highlands where wood r charcoal was plentiful and the iron ore of West thian and Midlothian was not too far distant. During e 16th and 17th centuries the shortage of charcoal was coming serious, and the expansion of coalmining ovided an alternative fuel; by the turn of the th century coal was in general use. The opening of deep workings in coalmines, made possible Newcomen's mechanical pump, assured a steady pply.

With this change-over proximity to coalfields became sirable, so in time the coal-producing districts became e producers of iron (and later of steel). As the old e fields were worked out and new methods of steel-aking which required high-grade ore were introduced, e industry became more and more dependent on ported ore with an iron content of 50–60% (compared ith the 30% of native ore), and consequently tended to ove to the great ports in South Wales, Tyneside, and e Clyde.

The chief ores are hæmatite (Fe_2O_3), magnetite e_3O_4), limonite (hydrated iron oxide), and iron carbon-te ($FeCO_3$).[7] The largest deposits in the world are the esabi fields round Lake Superior on the borders of anada and the United States; but the Swedish ranges, pain, and the Lorraine beds along the Franco-German order provide much of the ore used in Europe. In reat Britain, iron ore is mined from the deposits which xtend in a broad strip from the coast of Yorkshire outh-west to the coast of Dorset and also from the elds in south-west Scotland. Imported ore has, generally peaking, a higher iron content than the native deposit, nd so the costs of transport and smelting are less. bout a third of the ore now worked in this country is mported.

In Great Britain the industry is established in all the main industrial areas, with its greatest concentrations in South Wales, the north-east coast, Lanarkshire, and the west of Scotland, and a widely scattered Midlands group. All these areas are near coalfields, and there are heavy local demands for steel. In Scotland, where a seventh of the crude steel of the United Kingdom is produced, nearly all is used on the Clyde—a factor which determines the type of product made. Thus in 1943 a sixth of Scotland's crude-steel output was alloy steel for armour plate as against a twentieth in other districts.[9]

FALL AND RISE

During the 1920s and 1930s the British steel industry was faced with increasing Continental and American competition both at home and abroad, and many of its plants were out of date and inconveniently situated. The 1931 depression hit the industry so hard that in some areas two out of every five workers were unemployed, and output dropped from 9·6 million tons in 1929 to 5·1 million tons in 1932. In Scotland the output was only 30% of normal (fig. 1).

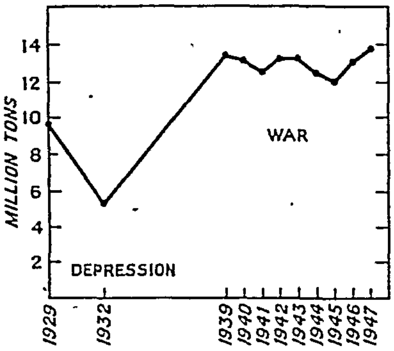

Fig. 1—Production in Great Britain of steel ingots and metal for castings.

During the inter-war period there was a decline in the number of insured persons in the five great basic industries—coalmining, cotton, wool, shipbuilding and ship-repairing, and iron and steel manufacture—and between 1923 and 1937 these industries lost 25% of their labour force. In some areas this was associated with a decline in the whole insured population. At the same time industries in some parts of the country were expanding, particularly in Greater London, which attracted many workers from other districts, and where the working population increased by 60% in the same period.

To stop the decline in the iron and steel industry the British Iron and Steel Federation was set up, with Government support, in 1933. A merging and disappearance of small firms produced a high degree of monopoly and led to the establishment of large new plants, some of which, like the Ebbw Vale Works in South Wales, helped to provide much-needed employment in distressed areas. This reorganisation of the industry was of the utmost importance in meeting the increased demands for steel in the late war. Fig. 2 shows the relative war-time production in relation to pre-war production[9]; and it may be noted that Scotland, which suffered more during the slump, made a greater

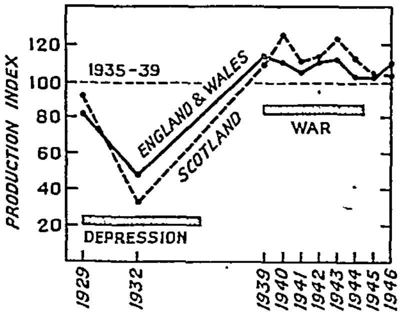

Fig. 2—Indices of steel production in Great Britain (1935–39 = 100. The average annual production in these years was 11,650,000 tons).

recovery than the rest of the country during the war.

In 1939–45 the British iron and steel industry handled 86 million tons of steel, of which 72 million tons was made at home. For this, 101 million tons of iron ore was mined, and 5 million tons of scrap obtained from three different sources—the national survey ($3^1/_2$ million tons), the salvage of steel from blitzed buildings (600,000 tons), and the conversion of iron railings (600,000 tons). The manufacture of the Bailey bridge is a good example of the way in which the industry rose to the demands of the Armed Forces. Production began in the summer of 1941, and by the end of the war over 200 miles of fixed, and 40 miles of floating, bridges had been produced by six hundred firms.[5]

In 1945 the "caretaker" Government called on the British Iron and Steel Federation and the Joint Iron Council to make recommendations for the future of the industry. In their report [17] the council drew attention to the desirability of further amalgamation of the smaller plants. To bring plant up to date, provide additional furnace capacity and new rolling-mills, and modernise iron foundries (where there is a serious shortage of labour), it was proposed that the enormous sum of £168 million should be allotted to capital expenditure over a period of five years. This would increase the production of steel ingots by 2 million tons a year, and of iron castings by 1–1·5 million tons. More recently, it has been estimated that the output of the industry can be increased to 18 million tons of steel a year by 1952.

Processes in the Industry

It is not easy to show where the iron and steel industry finishes and the metal and engineering trades begin. The absence of a common classification of processes makes comparison of industries difficult, and the fact that many iron and steel workers are ancillary to other trades adds to the confusion. The standard industrial classification of the Central Statistical Office [19] classifies the main processes of the industry as follows:

Order	*Process*
V—Metal manufacture	*Blast furnaces.*—Iron smelting and manufacture of pig-iron, ferro-manganese and spiegeleisen
	Iron and steel melting and rolling, including all processes of steel manufacture and casting
	Iron foundries.—All types of castings
	Manufacture of sheets and tinplate, including melting and rolling in integrated works, and the manufacture of galvanised sheets
	Manufacture of iron and steel tubes (all types)
VIII—Metal goods not elsewhere specified	*Wire manufacture,* including wire products made from both ferrous and non-ferrous metals

The industry can be divided into two main branches: (1) the manufacture of steel ingots and steel plates and castings; and (2) the manufacture of iron castings from foundry pig-iron. Fundamental to both these is the manufacture of pig-iron from the smelting of iron ore. The manufacture of tubes and wire from ferrous metals is also a branch of the industry. The iron-founding industry, which is concentrated in the Midlands with a large secondary producing area in Scotland, has an annual output of 2 million tons from 1750 foundries. These plants make a wide variety of foundry pig-iron, from which castings weighing anything from an ounce to 150 tons are taken. The present trend is towards greater standardisation of irons and reduction in the number of foundries, coupled with the replacement of s large capacity furnaces. The castings fall int main categories: (1) automobile and high-duty (2) building and domestic; (3) cast-iron pipes; (4) er ing and jobbing; (5) ingot moulds; (6) malleable ca and (7) railway equipment.

TABLE I—LOCATION OF THE STEEL INDU

Area	Chief industries	A
South Wales	Tinplate and sheet Billets for re-rolling Rails and sections	
North-East	Heavy commercial steel	(in joi tion
Midlands	Tubes, sheet, billets, wire and wire products	6
Scotland	Steel ingots, armoured alloys, iron and steel castings	2,

The steel industry proper includes blast furnaces billet, and plate mills; sheet and tinplate mills; section bar and strip mills; wire-rod mills; a manufacturers of joists, rails, and heavy-sectio These tend to concentrate in different areas as is in table I.

PRODUCTION OF PIG-IRON

In siderurgy the ferrous metals are classified a steel, or pig-iron according to their increasing c of carbon.[15] Wrought iron, like steel, is of low c content and malleable. Pig-iron is produced in a furnace by reduction of the metallic ore; this is with limestone and coke or coal and subjected powerful blast of hot air. The reduction is br about by the action of carbon monoxide, produce the partial combustion of the coke or coal, leadi separation of the metal from the ore with the forma of carbon dioxide. This is then reduced by more to form the monoxide again, so that the gases emer from a furnace may contain as much as 8% of car dioxide and up to 33% of the highly dangerous car monoxide. The exhaust gases are used for heating stoves connected with the blast furnaces and for rai steam for boilers. At intervals, the bottom of the furna is tapped and the iron run off into moulds or sand furrow where it is cooled and then broken up into lengths "pigs."

Once charged, a blast furnace is kept running co tinuously for years, only being stopped for repai For greatest efficiency it must be kept full of coke a ore, so continuous charging is necessary. Hand chargi has to a great extent been supplanted by mechani charging, but the work necessitates shift work on th part of the men in charge. The pig-iron produced in th way is used either for making steel or for iron-founding

MANUFACTURE OF STEEL

Bessemer Process

The modern manufacture of steel dates from Si Henry Bessemer's discovery, in 1855, of the process that bears his name. Today $7^1/_2$% of the steel output is produced in this way.

The constituents of pig-iron, such as carbon, silicon, and manganese, are altered in amount by blowing air under pressure through the molten mass, thus oxidising the various elements present. This oxidation generates great heat which produces the giant plume of flame of the converter "blow." The process can be controlled very precisely to produce different grades of steel, depending on how far oxidation has been carried. The whole process is carried out in a special furnace or "converter," which permits easy pouring of both metal and slag.

Bessemer process has undergone many changes since originally introduced, one of the most important being iomas modification to enable phosphorus-containing be used. Here the converters are lined with a basic ; and lime is added to the charge. This takes up the iorus in the pig-iron to form calcium phosphate, which a scum on the surface of the molten metal. This slag" is a valuable by-product, for it is used extensively artificial manure and also for the manufacture of ite of cotton"—a heat and sound insulating material ills of buildings. The Bessemer process is expensive ot satisfactory for the production of some types of steel oand today, and it is therefore giving way to the other ds of manufacture.

-hearth Process

e bulk of the British steel output—88½%—is produced by the Siemens open-hearth process.

-iron, together with iron and steel scrap, is melted bath-shaped furnace heated by a flame of coal-gas which s through the furnace from end to end together with a ir blast to produce oxidation. Each furnace may hold over a hundred tons of metal and take many hours to . Towards the end of the process more iron may be ed, and if this has to be fed into the furnace by hand, nen on this job are temporarily exposed to the intensely furnace contents. After tapping—in itself hot and heavy —the furnace floor may have to be mended by scraping filling in the holes and depressions caused by the melting ess. This is done with long steel rods called "rabbles" long-handled shovels, and the filling-in process itself is ned "fettling." This is extremely heavy work carried under trying conditions as the furnace is still red-hot after uring. Vernon[21] has estimated that an hour of continuous ling is more exhausting than eight hours' hand-charging blast furnaces. After fettling is complete, the furnace echarged and the whole process begins again.

ucible Process

Very pure steel for high-speed steel alloys cannot be oduced by the Bessemer or open-hearth methods, the crucible or electric furnace is used.

In the crucible process, which is gradually dying out, gh-grade iron is melted slowly in clay crucibles together with e metals required for the alloy. These crucibles are packed to coke furnaces, and formerly were lifted in and out by nd with the aid of tongs. The "teemer," or pourer, and the puller-out" were required to lift weights of well over 100 lb. uring the casting of the metal from the crucibles—an tremely hot and exhausting task.

lectric-arc Furnace Process

This is one of the most modern methods of steel oduction.

After charging, the furnace is traversed by a heavy current electricity which melts the iron and scrap as it passes rough, and temperatures of 3000–4000°C are obtained. ery fine steels are produced in this way.

As a result of improved mechanisation, and especially with fting and carrying cranes, much larger furnaces and ladles can now be used, and the mechanical charging of furnaces and improved methods of pouring have greatly reduced the physical wear and tear of smelting. Exposure to great heat is still unavoidable as men have to approach furnaces for testing, removal of slag, "puddling," and "fettling."

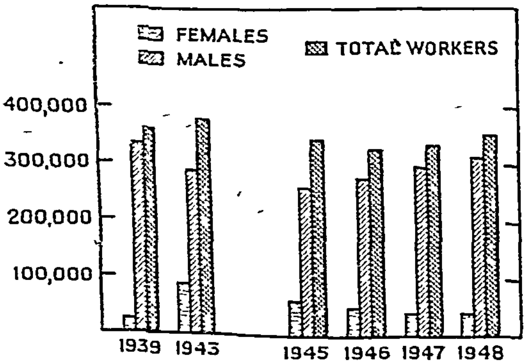

Fig. 3—Numbers employed in the iron and steel industry.

MANUFACTURE OF WROUGHT IRON

Wrought iron has a low carbon content and is malleable. It is made by melting pig-iron with slag and iron oxide, the molten mass being stirred vigorously with an iron bar to assist oxidation, a process known as "puddling."

The Labour Force

Between 300,000 and 400,000 people are employed in the main processes of the iron and steel industry.[14] The peak was reached in 1943 when about 368,000 people were employed, of whom over 80,000 were women (compared with 23,000 in 1939). By July, 1948, the total number of women in the industry had dropped to 43,500 (fig. 3), but judging from the trend of the figures over the previous three years it seems possible that the pre-war total of 23,000 may be permanently exceeded.

The proportion of skilled workers is not accurately known. The Registrar-General's decennial supplement of 1931,[16] in an analysis of some 270,000 workers in the metal-manufacturing trades—not necessarily all in the iron and steel industry—shows that 223,000, or 82%, were in social class III, indicating that they were skilled workers.

These trades are filled by apprentices, and today, apart from the over-all shortage of labour, there is a very serious lack of skilled workers. In the iron-founding industry alone there is an immediate need for 35,000 more people at once to fill jobs, many of which are highly skilled, and unless this increase is achieved plans for stepping up production in the next few years will be seriously embarrassed. The Joint Iron Council[17] noted that through the shortage of young physically fit men in the industry—due in part to the operation of the National Service Acts—the average age is now higher than at any time in the past; and the remaining skilled workers "on whom so much depends" are often not physically capable of producing a normal output. The depression of the early '30s saw a great falling off in the number of apprentices. The present rate of loss of workers exceeds the rate of intake of new workers, and it is evident that foundry work is not proving attractive to young men; while there is a shortage of workers and men can choose their jobs, foundry and other metal-manufacture work with its exacting demands does not attract recruits. It is difficult to see the answer to this problem; a long-term policy aiming at better environmental conditions will in time help to remove this handicap, but cannot ease the immediate shortage.

The metal-manufacturing trades include some of the highest paid workers in the country. During the last week in April, 1948, the average weekly wage paid throughout the metal, engineering, and shipbuilding industries was 144*s*., compared with 134*s*. for all workers; and the hours of work in these industries were only 43 per week compared with 43½ for all others. Within the iron and steel industry itself the highest wages were earned by tinplate and sheet workers with a basic wage of 3*s*. 7*d*. an hour, compared with 2*s*. 11*d*. for all others. The only advance on this, among all the industries listed by the Ministry of Labour, was that of fur-dressing, where the hourly wage paid was 3*s*. 8*d*. Therefore, in the metal industries long hours or low wages cannot be said to be the cause of the shortage of workers.

Because of the number of skilled workers, the problem of dilution during the war period was not easily solved. Mechanisation of such processes as moulding enabled the work to be done by unskilled or semi-skilled labour, some of it female, and the machine-made moulds could be turned out much faster than those made entirely by hand. Moreover, the opinion that the machine-made mould was as satisfactory as the hand-made—although not unanimously accepted—provides evidence that the lengthy apprenticeships for this and other crafts are unnecessary. This is important in view of the future inevitable shortage of adolescents and young adults resulting from the raising of the school-leaving age and the demands of National Service.

PHYSICAL DEMANDS

The iron and steel trades involve hard physical work, and the environmental conditions under which some processes are carried out increase the demands on the body. Exposure to extremes of temperature at furnaces and rolling-mills and in the open, and the inadequate winter heating in some of the older foundries together with constant draughts because of the absence of doors, combine to produce a most unfavourable working milieu. The work is not only hard but often hazardous and sometimes involves exposure to toxic material. Vernon,[21] in his investigation into the iron and steel industry after the 1914–18 war, classified all the processes he studied according to the physical demands, and showed that nearly all the actual productive processes involve intermittent heavy or very heavy work. Table II gives Vernon's assessment of some of the more important types of work.

TABLE II—CLASSIFICATION OF PROCESSES IN RELATION TO FATIGUE

Class of work	Process
Light	Control of gas-fed boilers Engine-room Weighers and checkers of blast-furnace barrows
Moderate ..	Rolling-mill machinery Mechanical filling of blast furnaces Mechanical moving and breaking of pig-iron
Heavy	Gas-producer men Iron-moulders Open-hearth steel-furnace men Rolling-mill men Crucible-steel teemers Boiler stokers Blast-furnace barrow men
Very heavy ..	Tinplate mill men Crucible-steel pullers-out Puddlers and fettlers Hand-charging open-hearth furnaces

Vernon points out that all arduous work is intermittent and that a good deal of time is spent resting in between bouts of charging, pouring, fettling, and so on. For this reason, the reduction of shifts from 12 to 8 hours did not cause a rise in output, as it would almost certainly have done if there had been gross accumulative fatigue. He emphasised, however, that fatigue varied inversely with the degree of mechanical efficiency; and he found very great variations in the efficiency of plants and employers. He found much out-of-date plant in some parts of the country, and commented on the unnecessary amount of weight-lifting due to badly planned layouts.

Vernon's investigation was made nearly thirty years ago, but a more recent inquiry has shown that the industry still has a long way to go before it can claim to have put its house in order. The Joint Advisory Committee,[13] in its report published in 1947, drew attention to three main objectives: (1) provisions of better amenities and more comfortable and healthy working conditions; (2) improvement in the appearance of iron foundries; and (3) improvement in the atmospheric

The accident-frequency rate is the number of accidents loss of working-time per 100,000 man-hours worked.

conditions by the prevention or removal of dust, and fumes.

The difficulties in providing a good standard of l in old out-of-date plants, where methods have c little during the last half-century, are great; but processes have been mechanised great improveme apparent, and thus hygienic considerations sho kept carefully in mind when new foundries ar built. For example, in foundries cramped w space is common, and rooms must be built large and high enough for work to be done safely. If c dust suppression cannot be achieved, special should be set aside for particularly dusty jobs, "knock-out" and "dressing operations."

ACCIDENT RISKS

The liability to accident in any industry dep a large number of factors, of which the most im are the type of process, environmental conditio age and sex of workers, and the safety organisatio plant. The compensation paid for reportable a in 1937 shows that workers engaged in iron a processes had an accident-rate of 90 per 1000 em compared with 58 for other metal workers, 50 fo and shipbuilding workers, 22 for other factory w and 200 per 1000 for miners. On the other ha ratio of fatal to non-fatal accidents was lower group engaged in extraction of metals than in an group with the exception of "other metal-work Significantly diminished death-rates from ac causes are reported by the Registrar-General fo groups of workers in the metal-manufacturing t

The figures for 1947 published by the Royal Soc the Prevention of Accidents [18] indicate that the ac frequency rate is significantly higher in the iron a trades than in the light-metal trades, the engi trade, or all trades combined (table III). Althoug are differences between the different branches of t

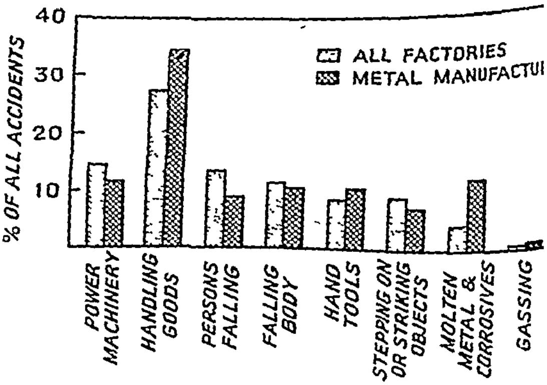

Fig. 4—Causes of all reported industrial accidents in 19

teel trades, the wide scatter of frequency-rates within ranch shows that these are probably correlated less the main type of process than with other and more ral factors.

metal-workers the pattern of accident causation not differ greatly from that found throughout stry in general. In 1946 metal-workers showed an ased rate from handling goods, from gassing, and accidents due to molten metal or other hot or osive substances. On the other hand, these workers fewer accidents from the use of power machinery, falling bodies, and from persons falling and stepping r striking against objects (fig. 4).

INDUSTRIAL DISEASES

he risk of contracting a specific occupational disease probably no higher in the metal-manufacturing ustry than in other trades, with the exception of lung osis and reticulation due to inhaling dust. In 1937 case-rate for industrial diseases per 1000 employed 0·7, compared with 0 6 among other metal workers, in miners, and 0·7 in other factories ; compensation s granted in 281 cases, of which 225 were new and 56 re carried over from the previous year.

Metal-workers are the main sufferers from some of the eduled industrial diseases. In 1937 this industry counted for 82% of all cases of industrial cataract, 0% of cases of nickel-carbonyl poisoning, 12% of ses of lead poisoning, 21% of cases of wrist tenonovitis, and (coalmining excluded) 33% of cases of beat hand " and 25% of " beat elbow." Silicosis and neumoconiosis are excluded from these calculations. he absolute numbers of cases of scheduled industrial iseases in iron and steel workers during 1937 were as llows :

Disease	*No. of cases*
Arsenical poisoning	1
Lead poisoning	24
Nickel-carbonyl poisoning	13
Dermatitis	109
Skin ulceration	3
Tar or pitch cancer	2
Chrome ulceration	3
Cataract	26
Beat hand	55
Beat knee	16
Beat elbow	3
Tenosynovitis of the wrist	26

Respiratory disease.—Sand-blasters and hand-fettlers r steel-dressers, whose job it is to clean castings by emoving the moulding-sand which adheres to them after ' knocking out," and grinders, who smooth off roughened astings with an abrasive wheel, are exposed to the risk f inhaling free silica from the sand on the castings, the sand of the sand-blaster, and particles thrown off by siliceous grinding-wheels. In general foundry-work the risk of silicosis is low,[13] but until abrasive wheels were made of substances containing no silica, and until the sand of the sand-blasting stream was replaced by steel shot, these workers showed very high death-rates for all respiratory diseases, and particularly phthisis. Of sand-blasters, the Chief Inspector of Factories wrote in 1933[3]: " Sand-blasting is the most serious silicosis-producing risk in the country, although of course not the most extensive." Of grinders, whose standardised death-rate for phthisis was 275 per 100,000 employed, the Registrar-General observed : " No occupation shows more clearly the progressive effects of siliceous dust inhalation upon an initially healthy body of men."

Steel-dressing is still a very dangerous job, for, generally speaking, there is no substitute for sand, and until moulds can be made of a harmless material the process of cleaning castings by hand tools is bound to produce a dust of silica particles. In a recent survey (personal communication) of nearly 100 foundry-workers in a steel plant, 75% of the dressers showed abnormal radiological chest findings and 40% definite pneumoconiosis, compared with 50% and 12% for grinders, and 40% and 20% for other workers. About a third of the whole group gave a past history of possible exposure to silica in coalmines, brickworks, or quarries.

The deaths from silicosis between 1939 and 1945 were as follows :

Industry	*1939*	*1940*	*1941*	*1942*	*1943*	*1944*	*1945*
Metal-grinding	19	24	13	13	11	7	11
Sand-blasting	13	13	4	4	6	7	6
Steel-dressing and cleaning of castings	4	4	9	9	4	10	5
All other metal-workers	403	481	380	391	449	421	486
(Coalmining)	(197)	(232)	(196)	(230)	(276)	(277)	(323)

For the reasons noted above, the risk of silicosis in foundry-work is now less than it was. Nevertheless, finely divided sand is constantly present and constitutes a menace in all cleaning operations ; and thus stringent safeguards have been laid down, notably by the committee appointed by the Ministry of Labour to investigate the problem of dust in steel foundries.[12] The Ministry's committee on iron foundries[13] recommended that wherever possible dusty processes should be carried out in separate rooms, so that the general atmosphere of the foundry should be kept as free as possible from harmful particles.

" *Dead hand.*"—A hazard to which workers using high-speed ripping, drilling, or grinding tools are exposed is " dead hand," or Raynaud's syndrome. In those using light rotary tools for metal-polishing the symptoms are rather different—pain, numbness, and swelling of the fingers. From recent detailed studies[1 2] it appears that the important factors are the speed of the tool and amplitude of vibration, the weight of the tool in the hand, and the heaviness of the work in relation to the size of the tool. A successful claim for compensation was made by a rotary fettler for disability due to Raynaud's disease on the grounds that the condition was brought about by a series of small " accidents " producing a cumulative effect (Fitzimmons *v.* Ford Motor Co., 1946).

Poisoning by noxious gases and fumes.—The commonest and most dangerous gas met with in metal manufacture is carbon monoxide. It is a source of danger in blast furnaces, coal-fired and coke-fired boilers, and gas-fired furnaces and melting crucibles, and wherever the combustion of coal or coke is carried on under enclosed conditions. In 1946, 117 cases of carbon-monoxide poisoning in factories, with 11 deaths, were notified to the chief inspector ; 20 cases, with 2 deaths, were reported from blast furnaces, and 42, with 6 deaths, from the use of power gas. Carbon monoxide is one of the most insidious of poisons, being both colourless and odourless, and each year cases of poisoning occur because it is present in an unsuspected place. Thus in 1946 a death was due to percolation of the gas through brickwork from a leak in a gas-producer plant ; another death resulted from the portable resuscitation apparatus being empty when it was wanted in an emergency.[4]

The smelting of metals and metallic ores may produce a variety of poisonous gases, of which the commonest are carbon dioxide, sulphur dioxide, and hydrogen sulphide. Many metallic ores contain arsenic as an impurity, and its sublimation as arsenious oxide may constitute a hazard. In the manufacture of steel alloys, the addition of other metals such as lead, manganese, and beryllium, some forms of which are toxic, introduces a health risk which is not present in the casting of pure steel. The workers most exposed to some of it female, and the machine-made moulds could be turned out much faster than those made entirely by hand. Moreover, the opinion that the machine-made mould was as satisfactory as the hand-made—although not unanimously accepted—provides evidence that the lengthy apprenticeships for this and other crafts are unnecessary. This is important in view of the future inevitable shortage of adolescents and young adults resulting from the raising of the school-leaving age and the demands of National Service.

PHYSICAL DEMANDS

The iron and steel trades involve hard physical work, and the environmental conditions under which some processes are carried out increase the demands on the body. Exposure to extremes of temperature at furnaces and rolling-mills and in the open, and the inadequate winter heating in some of the older foundries together with constant draughts because of the absence of doors, combine to produce a most unfavourable working milieu. The work is not only hard but often hazardous and sometimes involves exposure to toxic material. Vernon,[21] in his investigation into the iron and steel industry after the 1914–18 war, classified all the processes he studied according to the physical demands, and showed that nearly all the actual productive processes involve intermittent heavy or very heavy work. Table II gives Vernon's assessment of some of the more important types of work.

TABLE II—CLASSIFICATION OF PROCESSES IN RELATION TO FATIGUE

The accident-frequency rate is the number of accide loss of working-time per 100,000 man-hours worked.

ACCIDENT RISKS

The liability to accident in any industry de a large number of factors, of which the most i are the type of process, environmental condit age and sex of workers, and the safety organisati plant. The *compensation paid for* reportable in 1937 shows that workers engaged in iron processes had an accident-rate of 90 per 1000 e compared with 58 for other metal workers, 50 f and shipbuilding workers, 22 for other factory and 200 per 1000 for miners. On the other ratio of fatal to non-fatal accidents was low group engaged in extraction of metals than in group with the exception of "other metal-wo Significantly diminished death-rates from causes are reported by the Registrar-General groups of workers in the metal-manufacturing

The figures for 1947 published by the Royal S the Prevention of Accidents [18] indicate that the frequency rate is significantly higher in the iron trades than in the light-metal trades, the en trade, or all trades combined (table III). Altho are differences between the different branches o

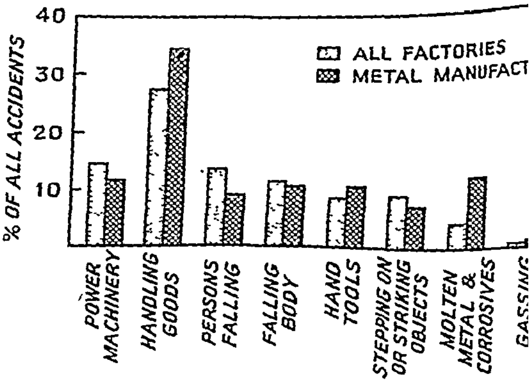

Fig. 4—Causes of all reported industrial accidents in I

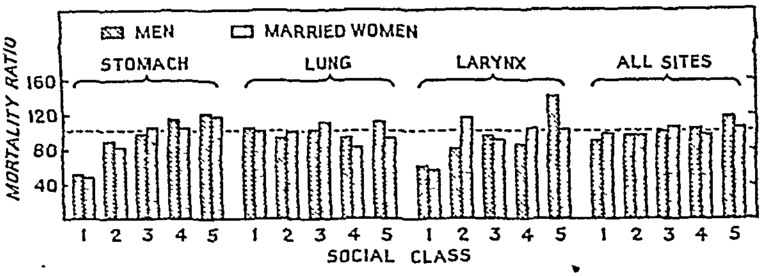

g. 6—Social distribution of standardised mortality ratios from cancer in iron and steel workers aged 20–65 in 1930–32, and in their wives. Death-rates for the whole population are set at 100.

ncer in certain sites. Grinders of metal (group 25) show particularly high rate for phthisis, mainly in the age-oup 35–65 years. Some of the deaths recorded as ue to phthisis in all these workers (with the exception of ire and tube drawers and makers, who are not usually xposed to a silica risk) are probably deaths from silicosis ith superimposed tuberculosis; but the figures recorded o not indicate the extent of silica fibrosis, which in many ases is the underlying pathology. The other respiratory iseases in table IV may also be regarded as risks of ccupation since no corresponding increase is observed n an analysis of the wives' experience.

Mortality from cancer.—The risk of death from phthisis and other respiratory disease may well decrease in the future, but there is no such assurance in respect of cancer. Excess deaths are observed from cancer of all sites, cancer of the buccal cavity and larynx, cancer of the lung, and cancer of the œsophagus and stomach (fig. 5). In all these sites, except the lung, there is a well-marked social gradient (fig. 6).

The most striking increase is in deaths from cancer of the larynx in men of social class V. Since there is no corresponding gradient for married women, the Registrar-General suggests that "the factors responsible for the excess of cancer of this site for unskilled males are directly associated with occupation." This may also be true of cancer of the lung, but is not so in regard to cancer of the upper alimentary canal where the experience of wives accords very closely with that of their husbands.

Using the Registrar-General's occupational classification, Turner and Grace[20] have investigated the cancer mortalities in men in some Sheffield trades between 1926 and 1935. They found that, while all steel-workers showed a significant increase for cancer deaths of the whole respiratory system and parts of the alimentary system, this was particularly so for foundry-workers. Cancer of the skin, although the deaths were few, is also relatively common among this group and in a high proportion of these cases the site was the scrotum or penis. The writers consider that skin irritation from sweat and dust-impregnated clothing is the probable cause. An increase in deaths from cancer of the pancreas was found in iron and steel workers and also in non-ferrous-metal workers, and they suggest that long-continued absorption of iron or copper may be the cause.

A further analysis of the occupational factors of possible ætiological importance suggests that there are three common to most of the groups involved—namely, exposure to heat, dust, or fume and gas, with a wide variety of agents in the last two categories. The cancers occurred at sites constantly exposed to irritants, and furnacemen and other metal-workers are exposed to various reputedly carcinogenic substances—for example, silica, steel grindings, iron oxide, and aluminium have all been found to produce an increased incidence of lung tumours in mice.[6] Kawahata[10] has reported an increase of lung cancer among generator-gas workers in iron and steel mills; these men were exposed to an atmosphere containing gas and a heavy dust, 0·7% of which was made up of coal-tar derivatives. Of the substances mentioned, it is doubtful whether silica or aluminium can produce lung cancer in man; but the increase in deaths observed in metal-grinders suggests a possible link between malignancy and iron, and the potency of coal-tar products appears to be established.

The two remaining factors common to metal-manufacturing occupations showing raised cancer death-rates are intermittent exposure to great heat and heavy physical labour. Both these will produce increased inhalation of irritant gas or dust by raising the rate of respiration. It may be that frequent breathing of hot air and gases is in itself harmful and capable of producing tissue changes. Cancer of the lung is a disease which appears to be on the increase throughout the population. How much of this increase is real and how much is due to improved diagnosis, it is difficult to estimate; but the raised death-rates in many trades must suggest the presence of important occupational factors.

SUMMARY

A survey has been attempted of the iron and steel industry in this country.

The manufacturing processes are described, together with the health hazards to which workers are exposed.

The accident and sickness experience, both occupational and non-occupational, of workers in the industry is discussed. Compared with other industries, there is a significantly high accident-risk, an increased liability to respiratory and locomotor disease; and many occupations within the industry show significantly high death-rates for cancer, particularly of the lungs and respiratory passages.

I am indebted to Mr. B. Woolf, PH.D. and Miss E. Duncan, M.A., for the statistical analysis of accident records and for assistance in the interpretation of mortality figures; and to Dr. R. Passmore for much helpful criticism.

these particular risks are the melters and pourers who come into close contact with the molten metal.

Dermatitis and skin ulceration.—Dermatitis due to the action of dusts or liquids is not a notifiable industrial disease, though voluntary notification is undertaken by many firms. The only accurate figures, therefore, are those relating to disabling cases when compensation has been paid. In 1937 the disablement case-rate was 0·23 per 1000 employed in the metal-extraction industry and 0·39 per 1000 for all factories. The principal causes are heat, friction with sand, oil, splashes of molten metal, and septic injuries.

Cataract.—Traumatic cataract due to continued exposure to molten metal occurs from time to time among furnacemen and casters. It is not a common disability, and with the increasing use of protective goggles and the mechanised charging of furnaces it should become even rarer.

The "beats" and tenosynovitis of the wrist.—"Beat knee," "beat hand," and "beat elbow" are trade names given to subcutaneous cellulitis at the knee, hand, and elbow-joint these conditions, and also tenosynovitis of the wrist, are caused by repeated friction combined with local trauma and infection. They are all predominantly diseases of miners, but they are also found to a small extent in other industries, notably heavy metal work.

MORBIDITY AND MORTALITY

The chief environmental factors likely to be reflected in the sickness experience of iron and steel workers are rapid changes of temperature, exposure to the weather, and the heavy nature of much of the work. A high incidence of rheumatic disease has been recorded among both smelters and foundrymen[11 21]; and this accords with the general experience that heavy physical work combined with frequent temperature-changes predisposes to locomotor disease. Heat cramps—a potential danger wherever hot and heavy work is being done—are not common, and are easily prevented by a proper fluid intake. The traditional preventive—beer—has today been largely superseded by the equally efficient, though perhaps not so palatable, saline drink.

Exposure to temperature changes and irritant matter inhaled in the form of dust or fumes are the probable causes of the high incidence of respiratory disease in furnace and foundry workers and those working in hot rolling-mills. Vernon[21] found that sickness absence owing to this group of diseases was increased in all iron and steel workers investigated by him, but was most pronounced among those whose work was largely done in the open, such as general labourers and barrow fillers. More recently Gafafer[8] has noted increased pneumonia-rates among steel-workers between 1939 and 1941.

The effect on the lungs of the continual inh of dust has been the subject of much research. 60 foundry-workers investigated by Keatinge,[11] showed clinical or radiological evidence of tuberc or silicosis; but in 12 of the men there was evide of dust changes in the lungs. Keatinge also found th while the workers in his series lost less total time f respiratory disease than workers in the constructi department of the factory, the average number of d lost per case was greater, indicating that the illnes were more serious in the former group.

Rheumatism and respiratory disease colour the pictu of the sickness experience of metal-workers in the occupations, but the Registrar-General's latest decen supplement[16] also shows increased mortality-rates f

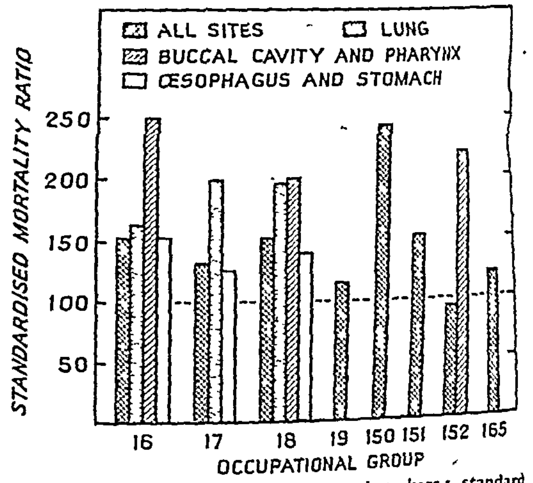

Fig. 5—Deaths from cancer in iron and steel workers: standard mortality ratios for men aged 20–65 years, 1930–32. Death-rates all males in the population are set at 100.

cancer. The Registrar-General's occupational gro do not always distinguish iron and steel workers fr other metal manufacturers and foundry-workers, there are so many risks common to all these work because of the similarity of the processes that they m be considered as integral groups.

The eleven occupational groups included in table have been surveyed. These groups comprise 257,2 male workers between the ages of 20 and 65 year of whom some 85% are placed in social class III as skill men, and 15% as semi-skilled in class IV (group or as unskilled in class V (group 152).

Many of these groups show significantly high mortali from respiratory disease, including phthisis, and fr

y (1946) also reported striking results from a long- experiment in Quebec Province. Among 38,188 ren immunised with diphtheria antigen and pertussis ne there were no deaths, whereas among the 145,494 ols there was a mortality of 19·2 from diphtheria 15·8 from pertussis per 100,000 specified population. (1948) not only reported good clinical results from bined diphtheria toxoid and alum-precipitated ssis vaccine in children aged 2 months or more, also claimed that immunity to diphtheria was nced by the combination.

PRESENT INVESTIGATION

erial

he London County Council residential nurseries ride about 700 places for long-stay (deprived) children short-stay children whose homes have temporarily broken. These nurseries are situated partly in metropolitan area and partly in the country; retically the former provide for short-stay and latter for long-stay children, but so heavy has been demand that in practice this distinction is scarcely d. Neither type of nursery can therefore be described closed community, since there is a constant trickle hildren being admitted and discharged. In common h similar institutions they have experienced numerous breaks of whooping-cough, which have seriously uced the efficiency of the nurseries. Table II shows incidence of whooping-cough in 1944–48 in the series included in the present investigation.

n 1946 the L.C.C. decided that, in view of the good orts from the United States, an attempt should be de to reduce the incidence of whooping-cough in these idential nurseries, and the advice of the Medical search Council was sought in framing the trials. It s decided (1) to use the combined pertussis alum- cipitated vaccine and diphtheria toxoid A.P.T. ccine A), prepared by Glaxo Laboratories Ltd., l as a control, an A.P.T. diphtheria toxoid (vaccine B), prepared by Glaxo Laboratories; (2) to select en residential nurseries according to their accessibility the North-Western Group Laboratories; (3) to exclude children who had already contracted whooping-cough who had previously been immunised against the ease; and (4) to divide the remaining children into ir age-groups: 3–6 months, 6–12 months, 12–18 nths, and 18–24 months. Within these groups alternate ildren should be given vaccine A and vaccine B. To eliminate possible bias in the subsequent diagnosis, none of the doctors or nurses were told which was the combined vaccine. The result was that two groups of children of about the same age and sex distribution were randomly selected, one of which was vaccinated against whooping-cough and the other was not:

B	13 (*8 3%*)	4 (*2·6%*)	10 (*6·4%*)	130 (*83·3%*)	156

Dosage

The inoculations began in June, 1947. In each group three doses, of 0·5 ml., 0·5 ml., and 1 ml., were given at four-weekly intervals. Altogether 648 children received injections, but records of 311 had to be rejected because the children were discharged before the course of injections was completed.

Length of Stay

For the children included in the final analysis the duration of stay varied considerably; some were still in the nursery in June, 1949, when the records were tabulated, whereas others had left within a few days of the completion of the course of injections. There was, however, no selection of members of either sample in relation to length of stay. Table III gives the figures for each group.

REACTIONS TO THE INJECTIONS

Table IV compares the reactions to each of the two vaccines.

Nodules.—At all doses the combined antigen produced nodules more often than did diphtheria toxoid alone. The differences are not large in view of the numbers involved, but in view of the consistency of the excess at each dose the results must be accepted as indicating that the combined antigen is likely to produce a more pronounced *local* reaction than the diphtheria toxoid alone. The incidence of a nodule at the first reaction in 1 child in 5 cannot, however, be regarded as a serious effect, more especially since persistence of a depot of antigen is obviously desirable. For both antigens the purely local reactions were less marked at subsequent injections than at the first.

Pyrexia.—Over-all the incidence of pyrexia was low and at the first dose was the same for both types of antigen, but at second and third doses there was a higher incidence of pyrexia for the combined vaccine. The differences at these doses are barely statistically significant, and in view of the lack of difference at the first dose the evidence is not so convincing as for nodule formation. The rises in temperature were not on the whole large; 99·4°F was a common figure quoted.

Malaise.—At the first dose malaise was a more frequent sequel for the combined antigen, but the difference in incidence was reversed at the subsequent doses. None of the differences is statistically significant. There is no evidence for regarding the combined antigen as more likely than diphtheria toxoid alone to make a child feel unwell.

EXPOSURE TO WHOOPING-COUGH

In such a fluid population and in the absence of full-time medical supervision, which was not practicable, it was impossible to keep a detailed check on the exposure of individual children to whooping-cough infection. But children in most nurseries mingle intimately indoors

SINCE the virtual eclipse of diphtheria during recent years whooping-cough and enteritis have emerged as the most dangerous, infections to children. The dangers of whooping-cough have been consistently underestimated, and it is usually bracketed with measles in the public mind as more of a nuisance than a menace; but Butler's (1947) survey showed that, though the incidence of whooping-cough, as disclosed by notifications in England and Wales, may be only a seventh that of measles, more deaths may result from whooping-cough because its case-fatality ranges from four to seven times that of measles. The figures for London from 1940 to 1948 confirm and emphasise this conclusion (table I) and show that, though there were almost three times as many notifications of measles as of whooping-cough, there were more than twice as many deaths from whooping-cough, the case-fatality averaging six times that of measles.

The attempt to prevent whooping-cough has had a chequered career. Since those who recover from the disease usually possess a lifelong immunity, it seems reasonable to suppose that, given an effective antigen, similar protection could be artificially induced. Various products have been used from time to time in the hope of establishing immunity. Madsen (1933), using a vaccine prepared from freshly isolated strains of *Hæmophilus pertussis*, was the first to report any success. His trials were made in the Faroe Isles during the epidemics of 1923–24 and 1929. He reported a mortality of 0·15% among the vaccinated compared with 2·4% among the unvaccinated. Sauer (1935) carried out extensive trials with a vaccine made from fresh virulent phase-1 organisms grown on human blood. He found that only 1·3% of 4906 vaccinated children, but 16·5% of 3460 unvaccinated controls, contracted whooping-cough. Kendrick and Elderling (1936) and Brooks (1940) also reported impressive results, again from the United States. Bell (1941) reported considerable success with an alum-precipitated pertussis vaccine, and Daughtry-Denmark (1942) gave convincing statistical evidence of the value of pertussis vaccination. Similarly favourable results were obtained by Cravitz and Cauley (1945), from the Boston Health Department, using Sauer's vaccine and a detoxified antigen; the vaccine ga high degree of protection.

TABLE I—MEASLES AND WHOOPING-COUGH NOTIFICATIONS AND DEATHS IN LONDON COUNTY

Year	Measles			Whooping-cough		
	Notifications	Deaths	Case-fatality %	Notifications	Deaths	Case-fatality %
1940	5447	29	0·53	669	10	1·49

1947	17,486	23	0·13	9267	83	0·89
1948	30,608	26	0·08	10,450	55	0·53
Totals	161,110	269	0·17	58,512	660	1·13

One of the few inconclusive reports from the Un States was that reported by Doull et al. (1939), used a vaccine in the preparation of which the suspen was washed with distilled water, a procedure which have caused deterioration of its antigenic pr. They reported little difference in the incidenc pertussis between immunised and non-immu groups of children.

In Great Britain, most of the few published re have been unfavourable. MacClean (1940) obta good results in laboratory tests and in a few cli trials of a contemporary commercial vaccine, McFarlan and Topley (1943) did not discover evidence of real protection from the vaccine they in a residential nursery in Berkshire. McFarlan e (1945) could not find any value in the immunisatio children in clinics and day nurseries in Oxford. B (1943) found Lederle's detoxified antigen ineffectiv hospital practice. One of the few favourable rep from this country has been that of Holt (1949) on field trials in Keighley with an alum-precipitated va among children, under the age of 5 years atten clinics, who had no history of whooping-cough.

One explanation of these discrepancies may lie i work of Leslie and Gardner (1931), who showed unless *H. pertussis* is in the smooth virulent ph antigenic variations are very likely to arise, and vaccines made from old rough cultures are espe likely to be disappointing. An alternative explan is that *H. pertussis* bears the same relationsh whooping-cough that *H. influenzæ* bears to influ the real cause of the disease being a virus. This op which does not lack suggestive theoretical supp difficult to reconcile with the reported success ach in immunisation with vaccines made from *H. per* since the cultural methods followed would be unlikely to favour the propagation of a virus. we are prepared to postulate some very unusual syn relationship between the virus and *H. pertussis*, the theory of causation seems to be untenable.

TABLE II—CASES OF WHOOPING-COUGH IN L.C.C. RESIDE NURSERIES

(*c*) Opened March, 1946. (*d*) Opened May, 1944.

Since the mortality from whooping-cough is high the youngest ages, the earliest age at which a bal be immunised is of considerable interest. Sako (1945) concluded that babies aged 2 or 3 months co effectively immunised against pertussis with an precipitated vaccine, as evidenced by agglutin titres. Sako (1947) provided further evidence same effect. Adams et al. (1947) also showed th immunisation of babies during the first few mon life was practicable. Meantime Sauer (1946), foll on the experiments of Schütze (1940), showed that possible to produce simultaneous immunisation a diphtheria and pertussis by combining diph antigen with an alum-precipitated pertussis va

INFANTILE PYLORIC STENOSIS

EW OF 100 CASES TREATED BY RAMMSTEDT'S OPERATION

. WARD-McQUAID B. Lond., F.R.C.S. SURGICAL TUTOR
BARBARA E. PORRITT B.A., B.M. Oxfd LATE HOUSE-PHYSICIAN, DEPARTMENT OF PÆDIATRICS
RADCLIFFE INFIRMARY, OXFORD

Rammstedt operation for pyloric stenosis in infants 1 to show results unparalleled by any other major tion; yet 100 consecutive Rammstedt operations tients in public wards of the Radcliffe Infirmary 38–48 were followed by no less than 11 deaths. urpose here is to analyse this series with special nce to complications and fatalities and to outline resent routine of treatment.

GENERAL ANALYSIS

le first-born infants are most often affected. In series there were 77 males and 23 females. Full y histories were available for 87 infants, and of 56 (64·4%) were first-born. The incidence according der of birth in the family was as follows:

1st child	56 (*64·4%*)
2nd child	13 (*14·8%*)
3rd child	11 (*12·7%*)
4th child	2 (*2·3%*)
5th child	2 (*2·3%*)
7th child	2 (*2·3%*)
8th child	1 (*1·2%*)

comparison, the Registrar-General's *Statistical Review England and Wales* for 1946 gives the incidence egitimate first-born children in the southern region, ch includes the Oxford area, as 41·2%.

he oft-noted *familial incidence* is illustrated in the ily histories of the 31 infants who were not first-born: ong these, 4 elder siblings had received medical treat- nt, and 1 had been operated on, for pyloric stenosis. two sets of binovular twins, where one was affected other was healthy.

he age of onset is usually 1–6 weeks, the incidence g greatest in the 2nd week, as the accompanying re shows.

preponderance of *breast-fed infants* is usual but in series the ratio of breast-fed to artificially fed nts was only 7 : 6. This is not necessarily significant, the number of breast-fed infants varies considerably different areas, and breast-feeding is often stopped the onset of symptoms.

acial incidence—The Anglo-Saxon race is most ceptible to pyloric stenosis, but the fact that all the nts in this series were of Celtic-Anglo-Saxon origin *f little significance.*

CLINICAL COURSE

The diagnosis of infantile pyloric stenosis is not ually difficult but requires a careful history and a orough examination, which must often be repeated to nfirm the presence of a pyloric tumour.

In a typical case the mother complains that the baby mits all its feeds, though its appetite is unimpaired, d that it is constipated and losing weight. Vomiting ually starts in the 2nd or 3rd week of life, but regurgi- tion may be present from birth, and is then followed projectile vomiting after 7–10 days. Bile is very ldom present in the vomit. Loss of weight and constipa- on follow, and frequent small green "hunger" stools on give way to one small formed stool every 2–4 days.

DIAGNOSIS

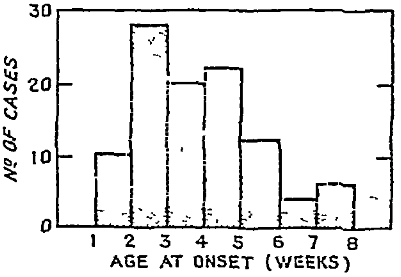
The diagnosis is confirmed by examining the infant hile it is being fed. Waves of gastric peristalsis are seen progressing across the upper abdomen from left to right. The hard mobile pylorus is felt, below the liver edge, with the flexed tip of the left middle finger, just beneath the outer edge of the right rectus muscle. As the feed continues, the baby appears restless and anxious and becomes obviously distressed. It then vomits, and the feed shoots across the floor and pours down its nose.

The findings may not, however, be conclusive, and the infant is then examined during its next and, if necessary, subsequent feeds. Gastric aspiration before a feed will often reveal a large residue and make palpation of the tumour easier. Provided the infant is in good condition, it is wiser to make these repeated diagnostic examinations without admitting him to hospital, thus avoiding the risks of intercurrent infection.

It is never permissible to give 'Eumydrin' as a therapeutic test, for the tumour may soften and never be felt, and the vomiting continues. A barium meal, and still less a diagnostic laparotomy, should rarely be necessary, if sufficient time and care are given to the examination.

Vomiting from duodenal atresia and other congenital causes of high intestinal obstruction starts from birth and the vomit usually contains bile; there is no palpable tumour, and the diagnosis may be confirmed by radiography. Acquired diseases, particularly otitis media, meningitis, and urinary infections, may cause vomiting in infancy; and pyloric stenosis may be present with any of these. The existence of pylorospasm as a separate clinical entity is regarded as doubtful, though there is a group of cases in which the vomiting is apparently functional.

In the present series a pyloric tumour was felt in 96 cases, and peristalsis was seen in 96 cases. Where one of these two cardinal signs was absent the other was present, except in one fatal case in which pyloric stenosis was doubtful. A barium meal was given only *four times*, confirming the diagnosis in 3 cases but not in the *fatal case just* mentioned. The average duration of symptoms before admission was 15·5 days for all the cases under review, and 10 days for infants admitted in 1948.



Age at onset of symptoms in 100 cases of infantile pyloric stenosis.

CHOICE OF TREATMENT

Medical treatment is used when vomiting starts late and is slight, for this is a self-limiting disease and its symptoms disappear at 6–8 months. Gastro-enteritis in the ward is another indication for a trial of medical treatment with the child as an outpatient. Treatment is carried out in the home to avoid the risk of intercurrent infection in the hospital. An intelligent mother is necessary for its success.

For all other cases operation is now the routine, for in favourable circumstances it carries a low mortality and is almost certainly curative, while the stay in hospital after operation need not be more than 3 or 4 days in an uncomplicated case, thus minimising intercurrent infections.

For the greater part of the period under review cases were admitted both to the surgical children's ward, where most of them were operated on, and to the medical children's ward, where a large proportion were treated medically. In the last three years, however, all the during the daytime and, as the records show, infection spreads readily. The incidence of whooping-cough in the nurseries (table II) indicates that a high proportion of the children included in the investigation must have come in contact with an infectious child. The figures for duration of stay and the method of selection of the two groups lead to the assumption that there can have been no difference in the risk of exposure between those receiving combined antigen and those receiving diphtheria toxoid only.

RESULTS

Of the 181 children receiving the full course of pertussis vaccine none contracted whooping-cough. On the other hand, among 156 controls 10 cases of whooping-cough were notified:

	Vaccine A	*Vaccine B*
Children receiving full course ..	181 ..	156
Cases of whooping-cough ..	0* ..	10

* One girl contracted whooping-cough after the first dose of vaccine A; she has been excluded from the analysis on the ground that she was not fully protected at the time of infection.

The probability that the whooping-cough cases would be concentrated in the unprotected group by chance is less than 0·001, and the result must be accepted as statistically significant. There is strong evidence that the combined antigen does give protection against whooping-cough.

Complement-fixation Tests

(DR. A. BECK)

Confirmatory evidence of the antigenic potency of the pertussis vaccine is provided by complement-fixation tests done in a random sample of cases. It is realised that complement-fixing antibodies are not necessarily a measure of real immunity against infection. The antibody titres are summarised in table V.

TABLE V—RESULTS OF COMPLEMENT-FIXATION TESTS ON 99 SERA

Vaccine	No. of sera giving titres * of								Total tested
	0	1/2	1/4	1/8	1/16	1/32	1/64	1/128

B	34	3	1	2	3	1	2	0	46

* The highest serum dilutions giving a positive reaction.

Antigen: Suspension of 10,000 × 10⁶ *H. pertussis* per ml. diluted 1 : 5 for test.

Technique: 0·1 ml. quantities of twofold serum dilutions, ranging from 1 : 2 to 1 : 128, are added with 0·1 ml. of antigen and 0·1 ml. of complement (3 M.H.D.). After incubation at 37°C for 1½ hours, 0·1 ml. of sensitised cells are added. Further incubation for ½ hour. End point is the highest serum dilution showing complete absence or only faint trace of hæmolysis.

It is evident from this table that the pertussis vaccine produced a good antibody response, 89% of children receiving this vaccine giving a positive reaction. When these tests are analysed according to the time between the final injection and the examination of the sera (table VI) it will be seen that, with one exception, all the negative reactors in this group were tested later than sixteen weeks after their final dose of vaccine, when the intensity of the reaction is known to be decreasing.

The incidence of positive reactions in children who did not receive pertussis vaccine is difficult to explain. They might be due to normal antibodies or to a previous subclinical infection. It is, however, significant that the falling off in titre with increasing duration from final dose, seen in pertussis-vaccinated children, is not seen in the control group; this in itself is further confirmation that the titres observed in the former group were the result of the injections and not of the chance factors operating in the second group. At all durations, however, the shift to the right is evident for vaccine as compared with vaccine B.

TABLE VI—SERUM TITRES ARRANGED ACCORDING TO SINCE FINAL DOSE OF VACCINE

SUMMARY AND CONCLUSIONS

During 1947 and 1948 a trial of vaccination whooping-cough was made in London's nurseries with the Glaxo combined diphtheria pertussis antigen.

The results show a significant difference in the of whooping-cough between the vaccinated and controls.

It is concluded that the antigen given con useful degree of protection against whooping-co No undesirable effects were noted.

The antigenic potency of the pertussis vaccine confirmed by complement-fixation tests, though conclusions can be drawn from these on the presence protective antibodies.

We wish to thank Dr. J. Ungar, of Glaxo Laboratories for supplying the antigen; Dr. W. C. Cockburn, M Research Council, for help and advice in framing the the doctors in charge of the nurseries; and Sir Allen D Medical Officer of Health for the County of London, for encouragement and advice.

"... Strictly speaking, science is a single entity: subdivision of science into separate branches is a matt convenience based on human limitations, which mak increasingly difficult for any one person to compass whole range. It seems a long way back to the days it could be said that the Bachelor of Science knew som the Doctor of Science knew *all*, or to the times when a such as Goethe could do effective research in anato physics, geology and botany as a part-time diversion his literary and other activities. ... The departmenta tion of science ... has led to serious confusion and los perspective. Nowhere is this more apparent than in field of mental science, where too often the diffe approaches, instead of complementing and broadening other, have resulted in futile rivalries and misunderstandin —Dr. DEREK RICHTER in *Perspectives in Neuropsychi* London: H. K. Lewis, 1950; p. 99.

ssibly occurred in another. A further operation nsidered where visible peristalsis and projectile g recurred after an operation at the fourth week, s infant had recovered under medical treatment tenth week. The duodenal mucosa was perforated ases, and the perforation was recognised and n with catgut. Nevertheless one of these children fever from the fifth to the sixteenth day, and ild died from a subphrenic abscess on the -third day.

1.—A Rammstedt operation was done under local esia; a tiny perforation of the duodenal mucosa osed with a catgut mattress suture. Postoperative s was not satisfactory; the wound did not heal; and in f parenteral fluids, including intravenous plasma the vent downhill and died on the twenty-third day. y revealed bronchopneumonia and a right posterior ritoneal subphrenic abscess containing 10 ml. of hich grew *Staph. aureus* on culture.

ment.—Death was due to subphrenic abscess. This d perforation of the duodenal mucosa, which had ecognised and repaired at operation. Possibly recog- and drainage of the subphrenic abscess might still averted death.

2 other occasions there was a "very doubtful ration" repaired with catgut: one of the children on the twenty-seventh day, not necessarily on this nt, and the other had a few days' fever in con- cence. An omental patch was used in another though there was no mention of perforation, and alescence was uneventful. Hæmorrhage from the ric tumour was noted 7 times—catgut stitches were 4 times, saline packs twice, and fibrin foam once d there were no ill effects. Such hæmorrhage can evere enough to be fatal. Two children who were ydrated and poor risks and who died within 24 hours peration may be said to have died of secondary k.

omplications occurring during anæsthesia were pro- e of the intestines and overdose of local anæsthetic. one infant there was sufficient "pushing" under l anæsthesia to cause prolapse of much of the intes- s, and the child suffered from severe shock but vered. There was no case of inhalation of vomit er anæsthesia, but one child died soon after inhaling it on the seventh postoperative day. Two children ived an overdose of local anæsthetic; one, weighing lb., became blue and cold during operation, under nl. of 1:1000 'Nupercaine' and 1:100,000 adrenaline local anæsthetic given by an honorary anæsthetist, caused no real anxiety and recovered; the other e 2) died.

ase 2.—A Rammstedt operation was done on a baby eeks old, in good condition and weighing 10 lb., under l anæsthesia given by the surgeon, who injected 20 ml. 1% procaine. The baby's condition was very poor two rs after operation; temperature 106·4°F, pulse uncount- e, unconscious, Cheyne-Stokes respiration. The baby d 7 hours after operation. Autopsy did not reveal the se of death.

omment.—The amount of procaine used (20 ml. of 1% tion) was three times what might be considered a e dose for this child. The postoperative course was sistent with that described in procaine intoxication.

Complications arising during convalescence were sepsis, morrhage from the wound, burst abdomen, and isional hernia. Superficial sepsis was noted 8 times, d deep suppuration twice. Local anæsthesia had en used in 6 cases, general anæsthesia in 2, and 2 ceived both local and general. The 6 cases in which absorbable buried sutures had been used healed eventfully. Hæmorrhage from the wound occurred the day following operation in 2 cases without ill fect; local anæsthesia had been used in both cases. One incision burst on the seventh day and was resutured, with recovery, and another infant developed an incisional hernia before discharge from hospital: these 2 paramedian wounds had been sewn up with difficulty by the same surgeon with catgut under local anæsthesia. There was an adhesion of the small intestine to the pylorus and to the wound at necropsy in one case, which showed how a volvulus or intestinal obstruction might later have developed.

Intercurrent complications during convalescence were gastro-enteritis, bronchopneumonia, and otitis media. Gastro-enteritis occurred 5 times, with 4 deaths. The discharge from hospital of a fatal case was delayed because the parents were mentally defective. One baby with severe bronchopneumonia recovered; and bronchopneumonia was a terminal event in 3 cases. Two infants required a mastoid operation during convalescence, and 1 was treated conservatively for otitis media; all recovered. Otitis media was found at necropsy in 1 case. Terminal inanition has been described as a further complication; 1 case could be classed under this heading. One infant developed osteomyelitis of the tibia *following a tibial drip transfusion.*

FATAL CASES

The causes of the 11 deaths were as follows:

Gastro-enteritis		4
Excess of local anæsthetic		1
Perforation of duodenal mucosa		1
Cause not definitely known		5
Poor risk, dehydrated infants dying within 24 hours of operation	2	
Terminal inanition	1	
Wrong diagnosis—terminal inanition	1	
Possibly incomplete division	1	

It is clear that many patients, especially the earlier ones, did not receive what would now be regarded as adequate preoperative preparation, with restoration of a normal fluid and biochemical balance. Their resistance to intercurrent infection was thus reduced.

Of these 11 infants 8 were breast-fed. Failure of medical treatment in 40 cases was followed by 4 deaths (10%), though it is more commonly followed by a higher mortality than in those cases treated originally by surgery.

COMMENT

A very comprehensive review of all aspects of infantile pyloric stenosis, and of the relevant published reports, was made by Szilagyi and McGraw (1943).

Levi (1941) reported on 100 consecutive breast-fed infants who underwent the Rammstedt operation without a death at the Infants Hospital, Westminster; in the same period 46 operations on bottle-fed infants were followed by 5 deaths, all from gastro-enteritis. Barrington-Ward (1937) gave the mortality at the Hospital for Sick Children, Great Ormond Street, as 18% in 1925; according to Paterson et al. (1941) this had fallen to 6·5% in 1939. Barrington-Ward (1943) states that 186 consecutive Rammstedt operations had been done at the Children's Nursing Home, London, without a death, and he ascribes this to the segregation and individual nursing of these private patients.

Ladd et al. (1946), in an account of 1145 Rammstedt operations done at the Children's Hospital, Boston, in 1915–46, gave the over-all mortality as 3·5%, with only 5 deaths in the last 557 cases, and no deaths in the last 225 cases. Donovan (1946), analysing 507 cases treated by the Rammstedt operation at the Babies' Hospital, New York, gave an over-all mortality of 1·8%, with only 2 deaths in the 389 cases treated in 1932–46. Schaefer and Erbes (1948), from the Milwaukee Children's Hospital, found 9 deaths in 232 Rammstedt operations done in 1924–47; there was no death in the 172 cases operated on in 1937–47.

infants have been admitted to the children's medical ward under the care of the pædiatrician, who has advised operation in most cases, and has been responsible for the preoperative and postoperative care of the infants. There has been a well-marked improvement in results.

The total number of operations each year, and the number following failure of medical treatment, were as follows, deaths being given in parentheses:

Year	*Total operations*	*Operations following medical treatment*
1938	9 (2)	3 (0)
1939	4 (0)	0 (0)
1940	4 (1)	1 (1)
1941	8 (0)	4 (0)
1942	5 (1)	1 (0)
1943	12 (0)	7 (0)
1944	4 (1)	3 (0)
1945	6 (1)	3 (0)
1946	14 (4)	12 (3)
1947	18 (1)	5 (0)
1948 (part)	16 (0)	1 (0)
Total	100 (11)	40 (4)

The numbers treated medically for infantile pyloric stenosis in the period under review could not be accurately estimated.

MEDICAL TREATMENT

Seven three-hourly feeds are given each day, preferably from the breast, but otherwise of any suitable artificial food, such as Half-cream National Dried Milk. 'Pylostropin' gr. $^{1}/_{750}$ is given 15 minutes before each feed, in a lamella placed under the infant's tongue; the daily total is just under gr. $^{1}/_{100}$. Older children receive larger doses. Stomach washouts are given only if the infant continues to vomit. The baby should be seen every day at first, so that, if treatment fails, he can be admitted for operation while still in good condition. If medical treatment succeeds, vomiting usually becomes less within twenty-four hours; treatment is continued until the child is at least 5 months old.

SURGICAL TREATMENT

Preoperative Care

All these babies are now admitted to the children's medical ward, and ideally mother and child are admitted to one cubicle. If this is impossible, the infant is isolated so far as is practicable. The restoration of fluid and electrolytic balance is regarded as urgent, but the operation itself is not an emergency.

Cases are grouped as those fit for immediate operation, those moderately dehydrated, and those grossly dehydrated. The first group are operated on when convenient, within twenty-four hours, and their only preoperative treatment is a stomach washout. Moderately dehydrated infants receive in addition frequent small feeds of water containing 0·225% sodium chloride and 2·5% glucose, and subcutaneous injections of physiological saline. Dehydration can usually be corrected within twelve hours, during which time up to 400 ml. of fluid can now be given subcutaneously.

The grossly dehydrated infants require intravenous fluid, which is usually given through a Keith needle tied into the long saphenous vein at the ankle. In gross dehydration the fluid-loss is equivalent to about a tenth of the body-weight; this is corrected with a mixture of equal parts of full-strength plasma and 5% glucose in distilled water. The infant's needs are then met by giving 0·225% NaCl and 2·5% glucose solution totalling $2^{1}/_{3}$ fl. oz. per lb. per day. The greatest improvement in the infant's condition is achieved after about 24 hours. The drip may then be continued during and after operation until the infant is taking sufficient by mouth.

Operation

The following procedure is most often adopted:

A premedication of atropine gr. $^{1}/_{200}$ is given, and the baby is bandaged to a padded crucifix splint. A bilateral rectus block and a weal for the skin incision are made, a solution of 0·33% procaine with 1 in 600,000 adre 15 ml. of this solution, which contains 50 mg. of p is certainly adequate and safe. There is no need to this dose for a 7 lb. baby, and indeed it may be dan to do so. A dummy soaked in equal parts of por glycerin keeps the baby quiet throughout the ope The tube used to wash out the infant's stomach is in during the operation, but it has occasionally been to withdraw air from a grossly distended stomach.

A high right paramedian rectus-splitting incision 2- long is made, and spurting vessels are tied with fine After the peritoneum has been opened, the pyloric tu delivered with Denis Browne intestine-holding forceps gently beneath the liver edge. The pylorus is rotated b finger and thumb, and the upper border, which is free vessels, is incised with a fine knife. The separation of the of the tumour is completed with a Denis Browne spreade the mucosa pouts through the whole extent of the in Particular care is paid to the duodenal end of the in to ensure complete division, while avoiding the s accident of perforation of the mucosa. Air is squ from the stomach through the duodenum to detec perforation; if one is found it is closed with catgut su Bleeding is unusual but may be controlled with a stitch. The pylorus is replaced in the abdomen, an peritoneum closed with a continuous catgut stitch. liver should cover the length of the incision, if this ha made high and kept small, but it may sometimes be nec to use a depressor for the lowest part of the wound. anterior rectus sheath is closed with fine catgut or ' sutures, the knots being buried, and the skin is close nylon stitches.

The 100 Rammstedt operations in the present were done by twenty different operators, but f these surgeons did more than half of them. In cases both morphine and atropine were given pre tively, though one or the other was occasionally o in earlier cases, and only atropine was given i recent ones. Local anæsthesia was used in 95 and in 10 of these had to be supplemented with g anæsthesia; in the remaining 5 cases general anæ was used from the outset. A high right param incision was used in the great majority of cases, a many of these the rectus muscle was split rather displaced. Midline and transverse incisions were used once only. Closure in layers was the rule, a most cases the buried sutures were of catgut. Una able buried sutures were used only 6 times; nylo used 4 times, and thread and silk once each.

Postoperative Treatment

Care is taken to prevent hyperpyrexia. The first is given 2 hours after operation, and consists of 1 dr of clear fluid. This is taken well after an operation local anæsthesia. Hourly feeds follow and are grad increased in amount; at the third feed breast-m given if available, otherwise Half-cream National Milk. The infant is put to the breast 36 hours operation if all is well. Feeds increase in amoun decrease in number, until on the third postope day the infant is on the correct 3-hourly feeding weight. If progress and home conditions are satisfa the infant is now discharged home. If postope vomiting occurs, it is controlled with stomach was and small frequent feeds. Stitches are remove the eighth postoperative day by the patient's doctor.

In the last 35 cases postoperative vomiting ceased, on the average, by the end of the postoperative day.

COMPLICATIONS OF RAMMSTEDT OPERATION

Complications arising during the operation in the pr series were incomplete division of the tumour, perfor of the duodenal mucosa, infection of the perit cavity, hæmorrhage from the pyloric tumour, and s Incomplete division was found at necropsy in one (under reflux) for an accurately timed 10 The liquid is then cooled rapidly, and when ransferred to a separating funnel containing NaCl, and extracted four times with 25 ml. benzene. The urine layer is now discarded nzene layers combined. The combined extract twice with 25 ml. portions of 9% Na_2CO_3 and s with 25 ml. portions of 2N NaOH to remove ubstances. The benzene layer is then shaken of freshly prepared 10% sodium hyposulphite a stoppered funnel until all red coloration , and is finally washed three times with 25 ml. distilled water. The solvent is then removed iced pressure at a temperature not above

esidue is added 0·5 ml. of dioxan, 0·2 ml. of O_4 and 0·25 ml. of 0·01N periodic acid. The allowed to stand at room temperature for s, additional 0·1 ml. portions of 0·1N $KMnO_4$ ed if the red permanganate colour is discharged. ion is then washed quantitatively into a sepa- nel with about 10 ml. of water and 30 ml. of id is thoroughly mixed. After the layers have he aqueous layer is discarded, any emulsion ned. One washing with 10 ml. of freshly % sodium hyposulphite solution destroys any anganate and breaks up any emulsion. This by three washings with 10 ml. portions of which the solvent layer is transferred to a and evaporated to dryness under reduced temperature not above 60°C.

Estimation

e is dissolved in 1 ml. of benzene; 0·2 ml. to a small tube, the solvent is removed l pressure, and 0·02 ml. of Girard-T solution e tube is rotated until all the residue has by the Girard-T solution, tightly stoppered, a boiling water-bath for 2 minutes. It is apidly and 2 ml. of the NaCl-NaOH base dded. This solution is polarographed at C), dissolved oxygen being removed by rogen through the solution for about 3 the wave height is not satisfactory (100 µg. d is the optimum amount) the amount of l for polarography may be modified. A recording polarograph is used in this labora- capillary used has an average drop time of d an average drop weight of 6·2 mg.

andard wave height is obtained by treating of isodehydroandrosterone with 0·02 ml. of solution, boiling for 2 minutes, and polaro- in the same way. Using a sensitivity where oamps gives a galvanometer displacement of the wave height obtained with 100 µg. of iso- androsterone is 17·5 mm. When using the same as continually it is only necessary to perform disation experiments about every two months.

tions

600 estimations have been done on hospital ts by the above method and the rather longer method (Barnett et al. 1946). The clinical value of of these estimations will be discussed in a paper published shortly.

CLINICAL OBSERVATIONS WITH DEOXYCORTONE AND ASCORBIC ACID

DAVID LE VAY
M.S. Lond., F.R.C.S.
ORTHOPÆDIC SURGEON

GEOFFREY E. LOXTON
M.B. Camb., M.R.C.P.
PHYSICIAN

WOOLWICH GROUP OF HOSPITALS

SINCE Lewin and Wassén (1949) reported their results with combined injections of deoxycortone acetate and ascorbic acid in rheumatoid arthritis—results we were able to confirm (Le Vay and Loxton 1949)—we have made observations in 80 cases of rheumatoid polyarthritis and also in monarticular varieties of this disease, in ankylosing spondylitis, and in osteo-arthritis. In another field, we have noted the action of these substances on painful stiff joints following injury and on localised post-traumatic œdema.

This report is chiefly concerned with the relatively transient clinical phenomena developing soon after single combined injections. Because it records the evolution and decline of this response, some importance may attach to the fact that all the injections on which it is based were given by one or other of us, and that in many cases progress was watched continuously for several hours afterwards. In some instances we have cinematograph records of the response.

TECHNIQUE

The technique originally employed was that initially described by Lewin and Wassén, in which 5 mg. of deoxycortone acetate in arachis oil is given intramuscularly, followed within five minutes by 1 g. of ascorbic acid intravenously (technique A). Later a single-dose intravenous technique was used, with an aqueous solution of 5 mg. of deoxycortone glucoside mixed in the syringe with the ascorbic acid (technique B). More recently we have been trying the effect of a single intramuscular dose of the oily deoxycortone and the aqueous ascorbic acid, mixed in and given with one syringe (technique C).

THE RESPONSE

In rheumatoid arthritis it is rare for there to be no response whatever at some time or other. In some cases it is dramatic, and apparent to the most superficial observation; and such a response provides one of the most exciting experiences of clinical medicine. In others it is slight but still recognisably of the same pattern. It not only varies from patient to patient but in the same patient from time to time. There are cases in which the initial response is barely appreciable but a second injection a week later is a dramatic success. The converse may also be true. In most instances the response is well established within an hour. In a few cases, using technique A, there has been a delayed reaction, coming on only after several hours. With technique B the response has usually been apparent within fifteen minutes. Technique C is as effective as the other methods; but, perhaps surprisingly, the response has been seen as soon as two or three minutes after injection, and in some cases the joint nearest the site of injection has been the first to show improvement.

The nature of the response has already been described (Lewin and Wassén 1949, Le Vay and Loxton 1949). Briefly, there is partial or complete disappearance of pain and spasm; an increased speed, ease, and range of joint movement; and a variable sense of exhilaration. A distinction must be made between measurable increase in joint range and the improved social performances allowed by the relief of pain and spasm; a patient with no great objective changes in the joints concerned may yet become comfortable enough to take off his coat, brush his hair, and climb stairs for the first time in many months. Though patients are often delighted with their

These workers differ in details of treatment. Levi (1941) does not believe in protracted preoperative preparation; he prefers local anæsthesia and uses the midline incision. The other workers emphasise the importance of protracted preparation and prefer general anæsthesia; the upper right rectus incision is used, except by Ladd et al. (1946), who prefer the oblique muscle-split incision described by Robertson (1940). Schaefer and Erbes (1948) are alone in emphasising the importance of diagnostic radio-opaque meals and routine postoperative blood-transfusions.

Jacoby (1946) treated 50 consecutive cases without a death; he selected medical or surgical treatment for each case according to definite indications. Medical treatment was successful in all of the 26 cases in which it was used.

The results in the present series compare unfavourably with those of the workers cited above, and afford little cause for complacency. This series is, however, reported with particular reference to the complications which may follow operation and, as a whole, does not indicate what results are being obtained at present. One reason for the high incidence of complications is the large number of surgeons concerned in these operations during the war years. Probably, however, these results are more representative of those obtained in this country as a whole, at least in hospitals where relatively small numbers of cases are seen yearly. Indeed, Aird (1949) goes so far as to say that in most centres the mortality usually varies from 12 to 25%. The remedies sought to lower the mortality in this hospital include early diagnosis before admission, isolation, and adequate preoperative preparation; premedication with atropine only, local anæsthesia, and gentle handling at operation; early postoperative feeding, and early discharge from hospital. Including 25 infants operated on after the series analysed above, there has been 1 death following the last 59 operations, and no death after the last 46. This indicates a more hopeful outlook for the future when compared with the 10 deaths in the first 66 infants in this series.

SUMMARY

A hundred consecutive cases of infantile pyloric stenosis treated in the public wards of the Radcliffe Infirmary by the Rammstedt operation are reviewed.

The routine management is outlined; all cases are treated by operation, except for those of late onset, or with intercurrent infections.

Local anæsthesia is used, and a dose of 50 mg. of procaine in 15 ml. is safe and adequate for a baby weighing 7 lb.

The complications arising during and after operation, and the 11 fatalities, are analysed.

The remedies sought to lower the mortality are outlined, and the need for isolation, adequate preoperative preparation, and early discharge from hospital is emphasised. There has been no death after the last 46 operations done at this hospital.

We wish to thank Dr. Victoria Smallpeice and Mr. A. Elliot-Smith for their helpful criticism, and the surgeons of the Radcliffe Infirmary for permission to publish the details of their cases.

RELIEF OF PAIN IN RHEUMATOID ARTHRITIS WITH TETRAETHYLAMMONIUM BROM

TREVOR H. HOWELL
M.R.C.P.E.
PHYSICIAN, GERIATRIC UNIT, ST. JOHN'S HOSPITAL,
CONSULTING PHYSICIAN, BERMONDSEY MISSION
LONDON

THE pain arising in the joints during acute [illegible] with the [illegible]hritis is one of the most [illegible] and [illegible] work being done [illegible] of rheumatoid arth[illegible] hope for the [illegible] all pains to relieve.[1] The [illegible] algesics [illegible] and adrenal hormones offer [illegible] avail[illegible] hitherto physical methods and [illegible] cases been the only forms of therapy [illegible] however, it has been found that t[illegible] bromide (T.E.A.B.) often relieves this [illegible] and sometimes for a considerable peri[illegible]

The origin of this form of treatment [illegible] statement[2] that "the nerve supply of [illegible] ligaments is derived from the sym[illegible] system." Since T.E.A.B. is known to bloc[illegible] impulses, it seemed rational to try its [illegible] pain. Accordingly 5 ml. of the solution [illegible] intramuscularly into an elderly man with an e[illegible] of rheumatoid arthritis in his hands. The r[illegible] within an hour, and he had no recurrenc[illegible] months. The next acute attack was treated [illegible] way and behaved likewise. The patient has no[illegible] from pain and swelling for five months.

Such a dramatic result led me to try th[illegible] T.E.A.B. in three male and twenty-three fema[illegible] with acute rheumatoid arthritis, with the[illegible] results:

	No. of cases	
No response	7	(only 1
No response 1st time, 2nd and 3rd times effective	3	
9 successive good results	1	lasting
4 „ „ „	1	„
3 „ „ „	4	„
2 „ „ „	4	„
1 „ „ „	6	„
Total	26	
	(55 injections	

Only one case with signs suggesting an [illegible] arthritis has not gained some relief from [illegible] seven cases which did not seem to be [illegible] no response. Three patients showed no [illegible] the first administration, but had freedom [illegible] after the second and third injections. Six[illegible] claimed either considerable relief or com[illegible] of pain for a time after administration. One [illegible] 9 successive good responses, one had 4, f[illegible] had 3, four had 2, and six had 1 satisfacto[illegible] The duration of freedom from pain varied [illegible] (in a woman who also had freedom from pain [illegible] and 21 days on other occasions) to 7 months. [illegible] of T.E.A.B. is usually felt within an hour [illegible] but in one or two cases the onset of r[illegible] delayed.

FAILURES

In the cases in which T.E.A.B. has not been [illegible] have usually found that the pain origin[illegible] circumarticular tissues and not in the joint. S[illegible] with massive fibrositis in addition to their r[illegible] arthritis state that their "soft-tissue" [illegible] worse by T.E.A.B., even when the joints [illegible] Patients with osteoarthritis do not seem to [illegible]

SUMMARY

T.E.A.B. has been given by intramuscular [illegible] patients with painful exacerbations of rheuma

ocorticotropic hormone (A.C.T.H.), treated 6 patients with no effect whatever. Douthwaite (1949) writes of urable results in 5 patients, while Fletcher et al. (1950) o good results in 9 cases. Robertson (1950) in 9 cases had ramatic response and improvement in all. Landsberg), with 9 cases, and Nashat (1950), with 4, both report ent results.

ter having had the privilege of seeing Lewin and sén's work at Gothenburg, we found ourselves in lete agreement on the clinical phenomena at issue, ow regard it as rare for a case of rheumatoid arthritis to respond at some time. The completely negative lusions of some workers may be explicable on three nds: (1) failure to appreciate small but typical onses in a series which does not happen to include bvious reactor; (2) the variation in response at rent times often found with hormone action, which, ondek (1935) says, is not absolute but depends on momentary condition of the organ and the physico-nical condition of its cells; and (3) delay in the onse. It may be that the intensity of the response is ly determined by the existing state of salt and water abolism, and in this connexion Spies's report may ide negative evidence in so far as all his patients e suffering from severe artificially induced salt vation.

ne is inevitably led to compare the effects of deoxy-tone and ascorbic acid with those of A.C.T.H. or ortisone.' In some cases the effect appears to be at st as dramatic as with the latter substances. Neither nch (1949) nor Lewin and Wassén claim to have veloped a new therapy for rheumatoid arthritis, but merely to have made physiological observations which may point the way to future treatment. It is possible that the method of Lewin and Wassén holds out the most immediate promise of relief to sufferers from this disease.

SUMMARY

In the majority of 80 cases of rheumatoid arthritis, deoxycortone and ascorbic acid reproduced the phenomena reported by Lewin and Wassén.

A similar response was obtained in monarticular infective arthritis, ankylosing spondylitis, and gonococcal arthritis, and benefit may be obtained in traumatic states.

Evidence is given for believing that the action of these substances is peripheral.

We wish to thank Ciba Laboratories Ltd. for supplies of 'Percorten,' of aqueous percorten glucoside, and of blank injections of arachis oil.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Obesity

On Jan. 24 the section of medicine met, under the airmanship of Sir ADOLPHE ABRAHAMS, the president, discuss obesity.

Dr. A. W. SPENCE remarked that obese patients were enerally referred as suffering from "some endocrine isorder," "pituitary dysfunction," or "hypothyroid-m"; but it was not so simple as that. Experience ith fattening animals would suggest that testicular eficiency led to obesity; but many eunuchoids were ot obese and testosterone had little effect. Whilst besity might occur in a patient with myxœdema, it as not the rule. Although obesity might develop in atients with hyperinsulinism and obese patients might xhibit low glucose-tolerance, there was no real evidence hat the ordinary case of obesity was the result of xcessive secretion of insulin; and Dr. Spence suggested hat diabetes and fatness might possibly be related to yperfunction of the adrenal cortex.

The pituitary was the gland usually implicated as the ause of fatness, but Dr. Spence rather thought this iagnosis was made when the real reason was obscure. He did not agree that hypopituitarism was a cause of besity. Simpson ascribed obesity at puberty and the enopause to hyperactivity of the anterior lobe, but Dr. Spence believed that it was more likely to be due to ts secondary effect on the adrenal cortex. With regard to obesity after pregnancy, it was known that during pregnancy there was hyperfunction of the pituitary and the adrenal cortex. He did not think that over-eating was responsible for obesity in many cases. He believed that the hypothalamus played a greater part than was generally thought, and that tumours of the pituitary caused obesity by pressing on the hypothalamus. Water retention might be present, and associated with it was diminished secretion of sodium chloride. This might be due to dysfunction of the hypothalamus.

In treatment the administration of the pituitary extracts so far available was valueless. For a reducing diet, Dr. Spence recommended a diet of low fat and carbohydrate content, and, because of its specific dynamic action, high protein content, in so far as this was now obtainable, to give an intake of 800–1000 calories a day; a vitamin concentrate of A and D; not more than 2 pints of fluid a day; and a minimum of salt. Where patients found it difficult to keep to a diet on account of hunger, he gave 5 mg. of 'Dexedrine' before breakfast, at 11 A.M., and at 4 P.M. Thyroid extract was rarely necessary, but might be given if the response to diet was unsatisfactory. Obese persons were often resistant to thyroid, and if they did not lose weight on 3 grains a day it was no good increasing the dose. Dr. Spence was not impressed by the effect on obesity of diuretics. Exercise, massage and purgation helped but very little. In children dieting should be avoided if possible—it was a hardship and it was doubtful if the child would keep to it—and the administration of thyroid extract was unnecessary if there was no evidence of hypothyroidism. A child might lose his excess weight spontaneously after puberty.

Prof. E. C. DODDS, F.R.S., agreed that thyroid extract was no answer to obesity, because so large a rise in metabolic rate was necessary to bring about a decrease in weight. Polynitrophenols were very dangerous. At an average hospital dinner in pre-war days—an annual dinner—700–800 calories would be consumed in the form of alcohol; to dissipate this by exercise a person would need to climb Ben Nevis at least twice.

The weight of an ordinary individual remained remarkably constant—the same to within a pound over long periods. That the weight of a normal person was reproducible to within $^1/_2$–1% showed that there must be an elaborate mechanism for its maintenance. The body appeared to be checking up against some external factor in the environment; and it seemed on general grounds that this external factor must be the gravitational pull. Professor Dodds had tried experiments to lessen the gravitational pull by attaching gas-filled bags, without new capacities, they exhibit no true euphoria. In some cases there is generalised decrease of sweating, with local warmth over the affected joints. Swelling, whether due to synovial effusion or periarticular œdema, may visibly shrink. The duration of the response varies between a few hours and several days, and is rarely as long as a week; but the end point is far from being as sharp as the onset. Though regression is usual, so that the disappointed patient may feel he is back where he started, some objective improvement is usually retained, particularly in the shoulders; and when the response to the first injection has been a particularly good one, this level of improvement is not far short of the best that is attained after subsequent injections. The results are better in the monarticular than in the polyarticular form of rheumatoid arthritis; and in the latter the shoulders, cervical spine, and wrists seem to react more favourably than do other joints. The action is non-specific in so far as active cases of ankylosing spondylitis and gonococcal arthritis respond in the same way. Osteo-arthritis, however, is not affected except in certain circumstances detailed below.

EFFECTS IN TRAUMA

We now wish to draw attention to some effects produced by deoxycortone and ascorbic acid in certain traumatic states—effects illustrated by the following examples.

1. A woman of 51 had fractured the head of her right radius nine weeks before and had a painful range of 70–150° at that elbow. Fifteen minutes after injection (all injections in this series were with technique C and given in the thigh) there was a painless range of 45–165° accompanied by intense local warmth at and around the site of injury.

2. A man of 58 had fractured his right external malleolus five weeks before. When the plaster was removed ankle motion was fair, but inversion and eversion of the foot at the subastragaloid joint were almost impossible and the attempt very painful. Fifteen minutes after injection there was a good easy inversion-eversion range estimated at 75% of normal, with only slight pain and marked local warmth.

3. A girl of 12 had suffered a minor displacement of her left lower radial epiphysis two weeks previously, and the range of wrist movement was between 15° dorsiflexion and 20° palmar flexion, with pain and apprehension and severe local tenderness. Fifteen minutes after injection she had a full painless range without tenderness.

4. A man of 55 had slipped while working on a roof three days previously, injuring his left elbow. An enormous hydrarthrosis developed, obscuring the normal contour, and there were only a few degrees of very painful motion. Thirty minutes after injection most of the effusion had subsided and there was a 45–120° range with only moderate discomfort. After this progress was rapid without further injection and recovery complete in ten days.

5. A girl of 13 had suffered a severe contusion of the right forearm muscles and as a result wrist movement was limited to a painful 20° arc. Fifteen minutes after injection she had a full painless range, and much of the swelling and tenderness of the affected muscle bellies had subsided.

Similar observations have been made in acute sprains of the ankle and the internal lateral ligament of the knee, in stiff painful wrists after Colles fractures, in stiff œdematous fingers after injury and tendon suture, and in impacted fractures of the neck of the humerus and lower end of the radius. The only instances of improvement in cases of osteo-arthritis have been when there was associated ligamentous strain and œdema, such as is often found at the inner side of the osteo-arthritic knee-joint. In general, the regression after the initial response is much less in traumatic cases than in rheumatoid arthritis, and sometimes a single injection suffices to clear up the whole condition, particularly in persistent localised post-traumatic œdema. There is a close resemblance to the action produced on the same conditions by blocking the sympathetic supply to the affected limb —e.g., the corresponding actions on local tem skin colour, and sweating.

SITE OF ACTION

We believe that deoxycortone and ascorbic acid peripherally, and not through the agency of the renal gland or other internal organs. Our reasons for belief are (1) that the response is so rapid, (2) that response is, if anything, more rapid with technique than either A or B, and (3) that with technique C response may appear first in the joint nearest the of injection. A simple clinical experiment was to decide this point.

We selected 10 cases of rheumatoid arthritis with more less symmetrical lesions. In the first 6 cases a sphygmomanometer cuff was placed on each upper arm and the pressure was raised to 80 mm. Hg. Into one forearm 5 mg. of deoxycortone glucoside and 1 g. of ascorbic acid was injected intravenously, and into the other 10 ml. of normal saline. The cuffs were maintained at 80 mm. Hg for fifteen minutes and the hands and wrists observed. In 5 cases there was no appreciable response in either hand and no general response was observed fifteen minutes after the cuffs were released. In 1 case there was a response in the hand on the side of the positive injection and no response in the control hand; but after releasing the cuffs there was a response in the control hand and one knee.

In 2 other cases 5 mg. of deoxycortone acetate in arachis oil and 1 g. of ascorbic acid was injected into the muscles of the upper forearm, and 1 g. of ascorbic acid alone into the other forearm, under similar conditions of venous occlusion. In 1 of these 2 cases there was a rapid response in the elbow on the side of the combined injection and a smaller response in the hand of the same side; on the side where only ascorbic acid had been injected there was no response until after the cuffs had been released. In the second case the result was indeterminate.

Unequivocal results were obtained in the last 2 patients.

In one, 5 mg. of deoxycortone acetate in oil was injected into the forearm muscles below an upper-arm cuff at 100 mm. Hg, and immediately afterwards 1 g. of ascorbic acid was given intravenously into the opposite arm, on which no cuff was applied. Within five minutes there was a dramatic response in the elbow of the cuffed arm, and the patient put her hand to her mouth for the first time in six years; nothing happened in any other joint. Five minutes after releasing the cuff the opposite hand, the shoulders, and one knee responded in the usual way.

In the second case there was symmetrical involvement of both ankle-joints. A cuff at 100 mm. Hg was applied below one knee, 5 mg. of oily deoxycortone acetate was given in the calf muscles of that side, and 1 g. of ascorbic acid was given intravenously in an arm. There was a rapid response in the ankle below the cuff, none in the opposite joint. After releasing the pressure the opposite ankle improved.

These findings indicate that the interaction between deoxycortone and ascorbic acid confined to the peripheral tissues is capable of producing all the observed clinical effects in the joints. This was well shown in the last 2 cases quoted, in which ascorbic acid was carried with the arterial flow into a limb containing a deoxycortone depot and from which the venous and lymphatic return had been occluded.

DISCUSSION

There is considerable disagreement among observers of small series of cases on the effect of this combined injection on rheumatoid arthritis.

Lewin and Wassén (1949) originally reported 9 successes in 9 trials, and we confirmed these findings in 21 of 23 cases (Le Vay and Loxton 1949). Kellgren (1949) had 1 dubious response in 6 cases and denied any benefit. On the other hand, Fox (1949) found that none of 10 patients failed to respond. Of the 17 cases of Hartfall and Harris (1949), 4 were worse, 1 better, and the rest improved only to the extent expected from physiotherapy. Lloyd Hart and Starer (1949) stated that the claims of Lewin and Wassén were not borne out in their 5 patients. Spies et al. (1949), in a comparison with ich therapeutic dose was the tracer dose, which ed urinary excretion and thyroid absorption to be sed. The quantity of isotope retained was measured tly on the patient. Only in a few cases did the our take up iodine. As a rule, neither primary cancer e thyroid nor its metastases were absorbing tissues, it was therefore necessary first to eliminate the al thyroid. This might be done either by surgery y therapeutic doses of radio-iodine, or by a combina- of the two. This procedure aimed at producing œdema, which forced metastases derived from the oid to concentrate iodine; but since the process was the possibility of keeping the patient going by the of ordinary X-radiation must be remembered. Once patient was ready for treatment by radio-iodine, the imum tolerable irradiation should be produced, as as possible, by a single therapeutic drink. Possibly, ever, only part of a tumour or one metastasis was tioning at any one time; and the tumours must a be destroyed by a series of treatments. The capacity absorb was reported to be increased by the use of rotropic hormones; but this had not been demon- ited in Manchester.

Dr. H. C. **Warrington** (Manchester) gave particulars the 21 cases of thyroid cancer treated at the Christie spital. Of these, 17 received tracer doses of I^{131}; only 2 were *tumours found to concentrate iodine,* d in both of these the tumours were metastatic. These cases received therapeutic doses of isotope after total yroidectomy, and were still under observation. In cases the tumour was non-functioning. Since it was lieved *that* after removal of the normal thyroid tissue e tumour might concentrate the drug, treatment was med at eradicating such tissue either by surgery or therapeutic doses of radio-isotope. In 10 cases there ere now signs of myxœdema; but in none had the mour yet acquired the ability to concentrate iodine. f the 2 tumours which took up iodine, one was highly ifferentiated with colloid formation, while the other was f Hurthle-cell type. Of the others, only 2 showed colloid ormation.

Mr. W. K. **Sinclair** reviewed the uses of radioactive sotopes for treatment of the internal surface of the ladder. For treatment a rubber balloon was inserted ato the bladder and inflated with a solution of radio- ctive sodium. For male patients a urethrostomy was equired, and in all patients the dose was about 3000 r ue to β-radiation and 3000 r due to γ-radiation.

Dr. R. J. **Walton**, reviewing the clinical findings, aid that of the cases treated by this method, all were pparently well at four months.

Dr. Walton then described a case of thyroid carcinoma which was referred to the Royal Cancer Hospital after a racheotomy had been performed. Tracer investigations with radioactive iodine revealed that the tumour was concentrating the isotope, and several therapeutic doses were then given—a total of 400 mC in all. The response was good; the tracheotomy was closed, and the patient was now well with no evidence of active malignancy.

Mr. C. J. L. **Thurgar** (Newcastle upon Tyne) described a surface applicator of radioactive phosphorus which had been used in the treatment of a malignant melanoma of the conjunctiva. A single estimated dose of 2000 r was given; a radiation reaction lasting forty-eight hours was observed; and the patient was well up to the present. The use of P^{32} in surface applicators was suggested for convex surfaces and for difficult sites, but not for general use.

Mr. G. W. **Blomfield** (Sheffield) described from the clinical standpoint a number of cases of thyroid disease treated with I^{131}; and he pointed out that the take-up of therapeutic doses in diseased tissue could not be accurately foretold from the take-up of tracer doses.

SOCIETY FOR ENDOCRINOLOGY

A.C.T.H.

At a meeting of this society on Jan. 26, with Mr. A. S. **Parkes**, sc.d., f.r.s., the president, in the chair, recent work on the constitution and actions of the pituitary adrenocorticotropic hormone was described by Prof. C. H. Li, of the University of California.

Professor Li, who has succeeded in isolating from the hormone an active mixture of peptides, observed that the hormone could be assayed on hypophysectomised rats in three different ways: (1) by repair tests of the adrenal cortex; (2) by the so-called "maintenance test," the hormone being able to maintain the body-weight and adrenal-weight after hypophysectomy; and (3) by the ascorbic-acid depletion test. A single dose of a.c.t.h. caused a prompt fall in the ascorbic-acid content of the adrenal cortex, followed after some hours by a very slow rise.

This hormone, continued Professor Li, had a half-*life time* of five minutes (compared with seven hours for the growth hormone); and it was destroyed by the adrenal, the kidney, and the liver. It stimulated production of all the adrenal steroids—the "desoxy-like," the 11-oxysteroids, and androgens and œstrogens. Animal tests had shown a.c.t.h. to have the following effects: (1) retardation of body growth and antagonism to the action of the growth hormone; (2) increase of nitrogen and potassium excretion; (3) increase in the free amino-acid content of the plasma; (4) glycosuria and hyperglycæmia in rats, but not in cats; (5) increase of body fat; (6) hypertrophy of the liver and increase of the liver fat; (7) increase of ketone bodies in urine and blood; (8) diminution of the plasma alkaline-phosphatase; (9) deterioration in chondrogenesis and osteogenesis of the tibia; (10) thinning of the epidermis, and atrophy of the sebaceous glands and the growing parts of the hair; (11) involution of the thymus and lymph-nodes, with depletion and dissolution of lymphocytes; (12) decrease of circulating eosinophils; (13) enhancement of work performance; (14) improved resistance, in normal rats, to cold, starvation, and low atmospheric pressure; (15) enhancement of adrenal regeneration in both normal and hypophysectomised rats; (16) inhibition of insulin effect on glycogenesis in isolated diaphragms of normal rats but not of hypophysectomised animals; and (17) inhibition of development of male accessories of normal rats but not of hypophysectomised animals.

This hormone, said Professor Li, was highly soluble in water; and in solution was strongly resistant to heat. No coagulation followed prolonged boiling in a neutral or *N*/10 acid solution. The molecule could, however, be broken down by heat treatment with the addition of strong acid and by pepsin; and an ether extract of the supernatant fluid, when dried, yielded a yellow powder. This powder contained a mixture of peptides which retained the original hormone's activity. But whereas the original molecule had a molecular weight of 20,000, these peptides had a molecular weight of about 1200 with an average amino-acid content of 8. The mixture could easily be fractionated; and on paper chromatography the "active spot" was 18 times more active than the original mixture. The individual peptides had all the beneficial effect of the original hormone; and perhaps a little more, judging by the ascorbic-acid test.

Professor Li concluded by listing the disorders which a.c.t.h. has been found to benefit. These include rheumatoid arthritis, rheumatic fever, nephrosis, glomerulonephritis, ulcerative colitis, asthma and other allergic disturbances, periarteritis nodosa, and virus pneumonia.

much result; and the opposite procedure—that is, weighting people down—was no use, because of the energy used to keep up the extra weight. The mechanism for the day-to-day control of weight was more elaborate than was realised, and if this mechanism could be discovered there would be a better chance of obtaining a response in patients.

Dr. **Raymond Greene** called for a shift of emphasis from fat retention to water retention. If one believed that "adiposity" was caused by the former, one was confronted by a series of insoluble dilemmas in the face of which one must either deny the law of the conservation of mass or else change one's belief. He preferred the latter alternative. Many clinical observations led to the conclusion that the essential point in the study of "adiposity" was the abnormal deposit, not of fat, but of water—a hypothesis which did not conflict with the law of the conservation of mass, and which accorded with the numerous experimental and clinical observations which put the blame on the hypothalamus—the seat of the nucleus supraopticus, which controlled water metabolism. He instanced particularly the "adiposity" which often follows encephalitis, concussion, and severe anxiety; and he quoted examples, pointing out the similarity between the increase in weight seen in women during anxiety and depression and that produced by Verney in dogs subjected to equivalent emotions. The excess of water appeared to reside chiefly in the adipose tissue.

He supported Dr. Spence in emphasising that neither thyroid nor anterior-pituitary deficiency was an important cause of "adiposity." In particular he pointed out that if the anterior pituitary was in fact concerned at all it was by overactivity, and that therefore the administration of anterior-pituitary extract was absurd: and that in any case anterior-pituitary extract was entirely destroyed by the normal processes of digestion.

Dr. **J. S. Richardson** described a small series investigated by Dr. H. J. Shorvon and himself at St. Thomas's Hospital as a result of finding a history of psychological trauma in two or three cases of pronounced obesity which did not respond to dietary restriction. The bombing of a home, the loss of a child, or the desertion or suicide of a husband had been followed immediately by rapid increase in weight. It was thought that this trauma might have led to impulses from the cortex acting on the hypothalamus to alter the water excretion and appetite, or weight control. There was no obvious psychological disorder, but abreactions produced a most intense release of emotion.

Altogether, 20 cases were under observation; and Dr. Richardson described the results of the investigation of 12 and the treatment of 9. They were a group of previously slim, young married women of average intelligence without previous neurotic illness who were mostly unhappy at home and had been rigidly brought up in sexual ignorance. All 9 patients who had had abreactions lost weight to an extent which, expressed as a percentage of their weight before treatment, averaged 13%. The average length of time taken to lose this weight was six months; and the average number of abreactions was twelve. Each of the 9 patients had lost over a stone in weight, although no other reducing method was employed; but one patient who had no abreaction did not respond at all to rigid dieting and dehydration. This loss of 13% could be compared with a loss of 23% in married women of the same age treated for the same time, as outpatients, with dietetic restriction and amphetamine.

Dr. Richardson made it clear that he and his colleague did not regard abreaction as a treatment for obesity. What they did say was that this method had shown that in some women obesity following traumatic incidents was associated with an extremely high emotional con that might well pass unrecognised since the patients not appear neurotic. They hoped that abreactions be helpful in managing certain selected cases.

Dr. **W. S. C. Copeman** thought that abnormalit body-fluid and adiposity need not be considered as separate subjects. He believed that in man, as in camel, the fat was the natural water-storage organ of body.

Radioactive Isotopes

A joint symposium was held by the radiology sec with the British Institute of Radiology on Jan. under the chairmanship of Dr. S. **Cochrane Sh** the section's president.

Mr. **N. Veall** discussed the uses of radioactive isot in measuring dynamic equilibria and the spatial di bution of ingested substances. As an example of first of these two uses, he quoted American workers had employed Na^{24} (half-life 12 hours) in studying rate of exchange between blood and body-fluids peripheral vascular disorders. However, the Med Research Council unit at Hammersmith had fo measurement of the time of exchange from blood body-fluids unsatisfactory, because the results influenced by changes in temperature and ext conditions. The reverse process was easier to meas the isotope was injected intramuscularly and the ra transfer from body-fluids to blood measured. For investigation of spatial distribution of the radioa isotope, Mr. Veall described a highly directional Ge Müller counter arrangement; with this it was pos to measure the distribution of radioactive iodine i thyroid gland. The same arrangement had been to locate the position of the placenta after a injection, and when the position was *later establ* by other methods the accuracy of the isotope test confirmed.

Mr. **Haigh** (Bristol) described a method for me ing the rate of fall in the blood-concentratio I^{131} in rabbits after an injection of the isotope. was led out of the carotid, passed round a Geiger co and back into the animal. The rate of counting recorded continuously on a rotating drum. He described a method for measuring an empirical cons of thyroid function, and an arrangement for measu the concentration of radioactive sodium in various p of the head.

Mr. **R. Marcus** (Liverpool), in a paper by himself Prof. **J. Rotblat**, described experiments to discover possibility of treating a case of multiple melanoma with radioactive copper and P^{32}. The copper, give colloidal form, concentrated in the liver only; but b tracer test, P^{32} achieved a concentration in the deposits ten times greater than that in normal ti Therapeutic doses of 5 mC and 15 mC of P^{32} were g Sections from the skin tumours showed necrosis, without radiation this was common in this ty disease.

Dr. **A. G. Macgregor** reviewed the extensive undertaken at Sheffield with radioactive iodine fo diagnosis of thyroid disease. The peak concentrati the thyroid, the time taken to reach the half-peak the urinary excretion, and the plasma clearance had all shown a degree of overlap between various g (normals, thyrotoxics, and others); but when concentrations of radioactive iodine in the plasma measured forty-eight hours after the dose, there wa overlap; in the diagnosis of thyroid disorders forty- hours after the dose had proved the most useful tim estimations.

Dr. **Ralston Paterson** (Manchester) observed the use of radio-iodine in cancer of the thyroid was on an entirely new principle. The essential prelimi

LONDON: SATURDAY, FEB. 4, 1950

Are the Beds Fully Occupied?

THE high and increasing cost of hospitals, and the essure for admission, have raised in many minds e question "could not something be done by nproving the proportion of beds occupied?" bviously, with total figures so large, even a small ercentage increase would mean that many more eds were in operation. Newcomers to hospital nanagement committees and regional boards are urprised and sometimes indignant to find that an verage occupancy of 80–85% for a fair-sized general ospital is often defended as satisfactory. After naking inquiries they quote other hospitals where he occupancy is reputed to be 100%; and from his point the discussion is apt to prove inconclusive.

The history of the subject is instructive. In the 890s, in his hospital annuals, Sir HENRY BURDETT nade many strenuous efforts to get to grips with it, and the definitions that were gradually evolved were ater taken over and used or modified by King Edward's Hospital Fund for London, and eventually in the *Hospitals Year Book* and the reports of the larger county councils. In the early 1930s the bed ccupancy of the big London hospitals was stated as about 83%, and though the figures for local-authority hospitals were often higher they were regarded with some distrust as an index of efficient management because they were thought to reflect overcrowding of the wards during part of the year. The Report on Unoccupied Beds made by the King's Fund in 1929–30 is now out of print, but in the absence of any more recent authoritative data the facts it gave are still of considerable interest. After pointing out that "beds temporarily closed" must be eliminated from the analysis before one can get at vacancies occurring between the discharge and admission of patients, it goes on to say:

> "A low all-over ratio of vacancy in the beds of a Hospital may cover a high ratio of vacancy in some beds through the operation of a very low ratio of vacancy in other beds. An inquiry into vacant beds therefore involves some segregation of the beds into various categories."

Clearly, as it remarks, "a high percentage of vacancy in beds reserved exclusively for accidents should not be criticised as showing that a hospital is not making the fullest effective use of its beds." and "it is to the interest of a Hospital, and an indication to some extent of its efficiency and health, that certain classes of beds should be as empty as possible." A table shows that when accident beds, isolation beds, pay beds, and staff beds were excluded, the average percentage of vacancy in the hospitals fell from 17 to 11. By pressing home the analysis in this way some striking discrepancies as between different hospitals in the same category were brought to light; for example, in the twelve teaching hospitals of London, arranged in random order, the percentages of open beds vacant were:

Hospital	*Medical*	*Surgical*	*Maternity*	*Gynæcological*
A ..	6·8	10·8	10·5	4·6
B ..	7·5	9·6	4·2	0·0
C ..	3·4	13·4	7·3	6·5
D ..	7·8	6·6	6·9	5·9
E ..	6·9	6·2	9·4	6·0
F ..	14·3	11·6	4·6	1·0
G ..	7·0	6·9	9·1	15·2
H .	12·2	16·3	0·0	7·1
I ..	7·0	18·2	12·4	11·1
J ..	9·0	11·1	12·0	10·5
K ..	2·2	1·9	0·0	0·0
L ..	5·3	7·3	10·9	5·7
Average	8·3	10·9	7·5	6·5

Similarly, an analysis showing the relative incidence of vacancy in beds allocated to men, women, and children in the medical and surgical wards revealed large differences in detail between comparable hospitals. For the same twelve hospitals the percentages of vacant open cots for medical cases were:

A	20·0	G	18·4
B	7·4	H	29·3
C	3·0	I	—
D . ..	10·3	J	12·8
E	8·2	K	2·9
F . .	17·9	L	8·5
		Average	14·3

It is thus abundantly evident that, as the report said, "a low all-over ratio of vacancy in the beds of a Hospital may cover a high ratio of vacancy in some beds through the operation of a very low ratio of vacancy in other beds," and that without close and detailed analysis no useful conclusions can be drawn.

Who can say whether or not the position today is much what it was in 1929–30? Maybe the Ministry of Health has the relevant figures in its archives: but so far as we are aware nothing has been published or found its way back to the hospitals in a way that would invite attention. The comparative statistics formerly produced by the voluntary hospitals, and to some extent by the larger local authorities in respect of their hospitals, were an external check—perhaps the only check—on each hospital's own ideas of what constituted a satisfactory standard; but the war years and the subsequent period of reorganisation and reclassification have upset the system. Inevitably, perhaps, the statistical and the financial sides of the Ministry tend to operate in separate compartments. But, if so, is it not high time for someone else to take a hand and throw a bridge from one side to the other by undertaking a fresh inquiry giving us figures comparable to those obtained by the King's Fund in 1929–30?

Reviews of Books

Epidemiology in Country Practice

WILLIAM NORMAN PICKLES, M.D. Lond., medical officer of health, Aysgarth rural district. Bristol: John Wright & Sons. 1949. Pp. 112. 10*s.* 6*d.*

THIS book, now reprinted in its original form, achieved immediate success on its first publication in 1939; and by 1941, when enemy action destroyed the entire stock and type, was regarded as certain to become a medical classic. This judgment needs no revision after the lapse of years. Pickles's simple yet careful method of studying infectious disease in Wensleydale, and his useful conclusions about the incubation period and duration of infectivity are now too well known to need description. Country practice seen through his observant eyes is packed with material for epidemiological observation, and his book, though short, abounds in the small glimpses of greater things which are apt to be missed altogether by the medical officer of health tied to an office desk. Consider for instance his remarks, made without comment, that he encounters an epidemic of measles about once every nine years, or that among a total of 56 patients seen during seven years with herpes zoster only 1 could remember having previously had chickenpox. The old assertion that no general practitioner can escape growing to know less and less about more and more is completely refuted by this book. There must be many in general practice who could apply the method of studying communicable and other diseases perfected by Pickles, and find it rewarding in a calling which is apt to be overfull of uncoördinated petty detail. They would at the same time be making positive contributions to the science of medicine.

The Neuroanatomic Basis of Surgery of the Autonomic Nervous System

ALBERT KUNTZ, PH.D., M.D., professor of anatomy, St. Louis University. Oxford: Blackwell Scientific Publications. 1949. Pp. 83. 16*s.* 6*d.*

Professor Kuntz has attempted the impossible task of condensing the anatomy and surgery of the autonomic nervous system into a short monograph. Perhaps no-one else could have done it so well in the space, but brevity is sometimes achieved at the expense of misleading over-simplification. It would be difficult for any reader without considerable previous knowledge to obtain an adequate picture from it of the autonomic innervation of any of the important structures in the human body; yet this is the essential basis for rational surgery. The illustrations, which are mainly diagrammatic, provide little additional help. A commendable feature is that, despite the title, physiology is often more fully described than anatomy. For a work designated as a monograph the bibliography is not exhaustive and is predominantly American, omitting any reference to the fundamental researches of Langley, Gaskell, Perman, Hovelacque, Braeucker, Lazorthes, and many others. More recent work on sympathetic pathways independent of the main sympathetic trunks is well summarised; but no mention is made of various other anatomical variations which help to explain the partial failure of some sympathectomies. The monograph is an interesting summary of an important subject and may stimulate surgeons to study larger works such as Kuntz's own textbook on the autonomic nervous system.

Resuscitation and Anesthesia for Wounded Men

The Management of Traumatic Shock. HENRY K. BEECHER, A.M., M.D., Dorr professor of research in anesthesia, Harvard University, and chief of the department of anesthesia, Massachusetts General. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1949. Pp. 161. 40*s.*

THIS book, the preface tells us, is a paste-and-scissors synthesis of various articles written by the author during his service with the American army in the campaign in Italy. It is in four sections, the first concerned with the mental and physical state of the wounded man, the second with the physiological derangements (i.e., the hæmatological and biochemical changes) of wounding, the third with resuscitation, and the fourth with anæsthesia for the recently wounded. Though ther nothing new to those with extensive experience casualty surgery, it is useful to have this record of hard-won lessons of war, set down in vivid American a man who not only was there but thought while was there. That most seriously wounded men are in pain and do not necessarily require morphine. the badly wounded cannot be resuscitated twic operation has to be postponed, that it is not necess to restore a low blood-pressure to normal before operat that spinal anæsthesia is a very dangerous and th pentone a dangerous anæsthetic in the recently wound —these things need restating often. This book is a us work for those treating severe injuries in civil life would be invaluable to a young generation of surge pitched into war without previous experience of special problems.

Advances in Carbohydrate Chemistry

Vol. IV. Editors: W. W. PIGMAN, University Alabama; M. L. WOLFROM, Ohio State Univers New York: Academic Press. 1949. Pp. 378. $7.5

THIS series is sponsored by an international editorial committee, and the authors of the various chapters are all acknowledged experts in their own fields. Vol. I appeared in 1945 and the structure and composition of vol. IV resembles those of its predecessors. Articles have been contributed by scientists in Canada, the United State the Argentine, Holland, and Britain, and some of th sections are of considerable general interest. The fir one, which deals with the structure and configuration of sucrose, is a good example of this, and the auth historical approach enables even those who are a litt out of date with their carbohydrate chemistry to foll the argument intelligently. Medical men with a thi for knowledge will also find much to ponder over the second section on the carbohydrate-amino complexe which are responsible for the A, B, and O blood-grou It is a far cry now to the days when the polysacchar in the animal body began and ended with glycogen.

Some other articles will appeal to all thinking men wh enough background of knowledge to understand them. Th problems involved in the saccharification of wood produ make interesting reading, and their importance is gr when one considers the enormous quantities of wood du and chippings which accumulate in the preparation of wood for commercial purposes. Some of the sections, however, are highly technical and specialised. The one on apiose and the glucosides of the parsley plant for instance can appeal only to a very limited circle, and the same applies to that on the acetylated nitriles of aldonic acids. The article on the plant gums and mucilages may interest dispensers and those who have to use these substances, but few of them will be able to grapple with the complicated chemical structure which has been suggested for their old friend gum-arabic.

Most of the articles contain a satisfactory though not an exhaustive list of references, and the book is one which many could consult with pleasure and profit for special points in teaching and research.

Rheumatism (2nd ed. London: Staples Press. 1949 Pp. 270. 17*s.* 6*d.*).—A note on the cover claims that, to brin his new edition completely up to date, Dr. Warren Crow has included a full description of advances in our knowledg of the rheumatic diseases and their treatment. The text however, does not support this statement. Though publishe in the autumn of 1949, the book probably reached the pre too early to carry any mention of the work on the relatio between the pituitary and adrenal hormones and rheumato arthritis; but the last reference given to any work by Henc is dated 1944. Dr. Crowe reiterates in a conversational styl his now familiar argument in favour of the infective origin of rheumatic diseases. Osteo-arthritis, he believes, has a mainly streptococcal, and rheumatoid arthritis a mainly staphylo coccal, origin; mixed forms can develop with mixed infection He continues to advocate the use of vaccines, and is at pain to explain why he does not consider controlled investigation into the efficacy of this method of treatment necessary. Th book is pleasantly presented and illustrated. References however, seem to have been selected more because the support the tenets of the Charterhouse Rheumatism Clini than for any other reason, and all the methods used at th clinic are described in great detail.

e trained psychiatric social workers are scarce, a large area had only one or two, with a team rained social workers under them. But this plan been found to answer well; for much of the k requires a knowledge of voluntary and other ncies, work opportunities in the district, recrea- nal and social possibilities, home-help schemes, ining prospects, and the like, rather than psychia- knowledge. In any difficulty the psychiatric ial worker, who kept in touch with the patient's n doctor, could see the patient herself, and get at advice seemed necessary. Encouraged by the ociation's reassuring name and reputation, people o had never needed mental-hospital care began seek advice because they feared a breakdown or re depressed or bewildered by the circumstances their lives: and here were opportunities—gladly ed—for genuine preventive work. The scheme anged from an aftercare service to a service of mmunity care for the maintenance of mental alth. A useful voluntary service, subsidised by overnment grants, was thus being built up when the ational Health Service came into action.

The Act unfortunately changed the position. ftercare became the legal responsibility of the cal health authorities, and the Government grants to he association for this work were withdrawn. The ssociation hoped that the local authorities would ubsidise the service, and allow it to pursue the work was already successfully doing; but this has nly happened in four places—the London area ncluding Middlesex and West Ham), Newcastle, nd Birmingham and Kent (which are changing the rrangement). Elsewhere the local health authorities ll elected to do this work themselves. Of the difficulties facing them, the most formidable is hat many patients will not bring their intimate personal troubles to a statutory body—and how many reject the opportunity can never be assessed. Again, the authorities have special staffing difficulties; they are obliged—and indeed glad, no doubt—to fit into the new service people who have been with them for many years holding posts as reliev- ng officers. These—now the "duly authorised officers" of the day—are many of them first-class people, with a long record of good service; but they have not been trained in psychiatric concepts, and are inclined to think them far-fetched. Moreover, they are oriented to local-authority service, which means they like things to be done duly and in order; they have lost, perhaps, some of the pliancy which is needed in dealing with people whose minds are a little sick. At all events psychiatric social workers are not at present responding very readily to the advertisements of health authorities, perhaps feeling that they could not easily build up the same team spirit inside the municipal service as was possible in a voluntary scheme. It is true that psychiatric social workers seconded to local health authorities have often been able to establish excellent working relations with their new colleagues and to interest them in a different approach to mental health; and clearly much progress can be made in this way. But it must also be admitted that a successful mingling of the old and the new can be achieved only when good will, and perhaps exceptional qualities, are to be found on both sides.

The closing down of the association's centres has meant hardship for patients in many parts of the country, as their letters to the association only too painfully testify. Those mental hospitals which counted on the association's help are also feeling their loss.

> "One great difficulty which social workers have found since July 5, 1948," writes Dr. LOUIS MINSKI, in the annual report of Belmont Hospital for 1948–49, "is the obtaining of social histories in respect of patients living in distant parts of the country. This work was formerly undertaken by psychiatric social workers from the National Association for Mental Health and in most cases they have now ceased to function. Nowadays there is often no psychiatric social worker available in the district where the patient lives and the local M.O.H. has to be approached. He may have no-one on his staff with experience of psychiatric work and the report is often of little or no value. Similar difficulty is also being encountered in arranging aftercare for patients because of the lack of psychiatric social workers. In some districts aftercare consists in referring patients to a psychiatric clinic which may be the last thing which is required. I am afraid aftercare as understood by us in the hospital has almost ceased to exist."

This loss is very serious, and it is regrettable that a useful going concern should be allowed to melt away when we have nothing to replace it. Even though the local health authorities may in time develop an excellent service, the outlook of the mentally sick will have to be changed before this succeeds in reaching all who need it. Voluntary care is here the more appropriate method; and, if the local authorities are unwilling to maintain the association's work, surely one of our rich voluntary funds could come to the rescue? The service has never been expensive: it has been run with the smallest possible outlay. But it has prevented a great deal of avoidable distress and restored to active work many people who would otherwise have remained despairing and useless. To keep and advance such an enterprise as this, funds should surely be forthcoming.

Continental Jubilees

JUBILEES are celebrated by two Continental journals with their opening issues this year. The *Wiener medizinische Wochenschrift* first appeared in 1851, since when the scientific world has learned to associate Vienna and its medical journal with such names as Hebra, Chvostek, Billroth, Virchow, Ehrlich, Lorenz, Freud, Eiselsberg, Wagner-Jauregg, Economo, and Pirquet. This journal had an early link with the younger *Deutsche medizinische Wochenschrift* through the publication in each of Robert Koch's article Über die Cholerabakterien in which he replied to the many criticisms of his work. When the German journal was founded by Paul Börner in 1875, Robert Koch was still an unknown country doctor whose wife had lately given him one of those new-fangled microscopes as a birthday present. Börner was quick to recognise the importance of Koch's work; and the journal's early fame was largely due to its publication of the classical investigations of Koch and his disciples—Behring, Brieger, Ehrlich, and Pfeiffer. After the advances in bacteriology and immunology at the end of the 19th century came the age of the great clinicians who applied them. Here again the *Deutsche medizinische Wochenschrift* played an important part, interpreting to the medical profession in Germany the techniques of the New World; and chemotherapy brought the tide of discovery back to Germany when Domagk's first paper on 'Prontosil' appeared in 1935.

Boric Acid Poisoning

Boric acid has long been used as an antiseptic, though its germicidal value is very slight and *Staphylococcus aureus* survives long exposure to a saturated solution.[1] Both boric acid and sodium borate have some bacteriostatic action, but Sollmann[2] questions whether under clinical conditions solutions of these substances check bacterial growth at all.

The purposes for which they have been used are many. Thus Ross and Conway[3] have no fewer than forty, ranging from the familiar eye lotions, douches, and mouth-washes to the now generally illegal use as a food preservative and the uncommon empirical use of sodium borate in epilepsy. Boric acid is regarded as a mild, bland antiseptic, and there is hardly a part of the body to which it has not been applied. That it is toxic when taken by mouth is fairly well known, though even this was not appreciated by twenty out of thirty doctors who were questioned.[3] Its toxicity from external application is less widely known, though severe poisoning and deaths have resulted from its employment in this way. According to Ross and Conway, the first fatality was reported in 1883, when a man died from 5 days' application of boric-acid powder to a sore on the leg.[4] Other deaths have been due to irrigation of septic cavities,[3] administration in enemas, and application as a burn dressing[5] and in the treatment of widespread eczema,[6] to mention only a few instances. Accidental ingestion —for example, by mistake for a saline purgative[7]— has been reported from time to time, and in one baby death was due to borax and honey given for thrush.[8] At least one breast-fed infant has died as a result of boric acid being used to cleanse the mother's nipples[9]; and in an epidemic of diarrhœa in a neonatal ward the evidence strongly suggested that the infecting organisms were conveyed to the infants by the pledgets of cotton-wool soaked in boric-acid solution used for cleansing the nipples of the nursing mothers.[10] It is among infants that the death-roll has been highest. Ross and Conway traced twenty deaths up to 1943, since when a further twelve have been recorded; and about half of these deaths—to which others could be added—have been of children under the age of 2 years. The most recent report[11] concerns a tragic accident in hospital, when six babies, aged 6–11 days, died because a 2·5% aqueous solution of boric acid was used in place of sterile water in preparing feeds. The infants died between 19 hours and $3^1/_2$ days after a single feed prepared in this way; the fatal dose was thought to have been less than 3 g. The lethal dose seems usually to be 5–6 g. in children and 15–20 g. in adults, but wide variations are recorded; one woman, for example, showed only mild toxic effects when given 15 g. intravenously.[12] Repeated doses, by whatever route, have a c lative effect—a fact which has led to the ba of boric acid as a food preservative.

The main signs and symptoms of poisoning those of gastro-intestinal irritation—nausea, vomi epigastric pain, and diarrhœa—accompanied increasing shock and ultimately collapse. Convulsi have been reported. There is an erythematous ra which may be very pronounced, and which is follo by desquamation. Death may take place up to 5 da after a fatal dose. Treatment, according to Pfeiffe and others,[13] consists in administering intravenou large doses of saline and plasma. Post mortem th usual findings are inflammation of the alimentar tract, toxic degenerative changes in the liver an kidneys, and cerebral œdema. Boric acid i concentrated most highly in the brain and the liver.

Boric acid is to be found in so many domestic medicine cupboards, and it is used so much, without special care, *in hospital, that it is really* surprising that there are not more cases of poisoning. It bears no poison label; and in the U.S.A. an attempt to insist on such labelling failed.[14] Hospitals can, however, make their own arrangements for marking solutions; and this precaution is particularly important in maternity wards. But is it necessary to use boric acid at all? In Watson's words[6] "When a drug can be shown to be almost entirely ineffective and at the same time dangerous, even when used in ordinary ways, it is time to remove that drug from general use as rapidly as possible."

The Future of Community Care

Aftercare probably has a more important place in the treatment of the mentally ill than in that of any other type of casualty. The patient who leaves a mental hospital well enough to go home is seldom ready for the impact of ordinary responsibilities: his shattered self-confidence needs to be carefully restored, and relatives have not always been well enough prepared to help in this task, or even to realise how necessary it is. The visits of a psychiatric worker at such a time can make all the difference between consolidation of his recovery and a fresh breakdown—not because she attempts any "therapy" as such, but because she will explain his needs to the family, let him unburden his fears and hopes, help him to find the work he is fit for, see that he gets whatever grants or allowances are his due, stand by him in times of tension, and reassure him of his human value. It is important work which cannot easily be done through official channels; for it must maintain or establish contact with the man whose complaint is merely that he is afraid of life, or that he fears to become suicidal again, or that he is obliged to refuse the job his friends are pressing on him, because it is on the ninth floor and he dare not use a lift.

During the war, at the request of the Board of Control, the National Association for Mental Health started an aftercare scheme for Service psychiatric casualties, which was such a success that it was afterwards extended to civilian cases, and by June, 1948, was well established throughout the country.

far we have only one true example of this process, absorption of I^{131} in functioning cancer of the roid—a small gain in itself but one which opens a inating field of research.

NOMENCLATURE OF FUNGI

HE nomenclature of the medical fungi, never satis-tory, has been complicated by the indiscriminate ning of new names; mere mutants have been accepted l named as new species. Thus an unwieldy synonymy grown up. Diddens and Lodder have cited 87 nonyms of *Candida albicans* (Robin 1853) Berkhout 23, the common thrush fungus; while Conant puts number at 172. Fortunately, few of these synonyms to be found in current works; but misunderstanding sometimes caused by the use of two entirely dissimilar mes for the same species—e.g., *Monilia pinoyi* for *ndida albicans*, *Torula histolytica* for *Cryptococcus oformans*, and *Microsporum felineum* for *Microsporum nis*. The decision on what is the valid name of a ngus must accord with the international rules of tanical nomenclature; and careful research is needed establish priority.

The medical mycology committee of the Medical esearch Council has done a useful service in preparing list,[1] of names recommended for the fungi pathogenic o man and animals in Great Britain. The list gives the pproved names of the fungi with the authorities and the nore common synonyms, and the names and synonyms f the associated diseases. There is regrettable lack of greement on nomenclature between different countries, nd even among groups of medical mycologists in he same country; and the publication of this authori-ative list is a step—albeit a small step—towards securing ational and ultimately international agreement.

ULTRA-RAPID TRANSFUSION

A method of giving blood or infusion fluids very rapidly, y forcing them out of the transfusion bottle with xygen under pressure, is described by Pierce, Robbins, nd Brunschwig.[2] These workers have used this method o administer blood to patients who have collapsed luring extensive surgical operation, transfusing it at ates varying from 100 ml. to about 250 ml. per minute. he need for rapid transfusion in profound "shock" lue to hæmorrhage or trauma has been appreciated ince the late war,[3] but in this country blood is seldom given at rates much above 100 ml. per minute. Faster restoration of a depleted blood-volume may have certain advantages, but the dangers of air embolism[4] and "overloading"[5] associated with rapid transfusion are likely to be increased. If embolism is to be avoided, the oxygen propulsion method requires the full attention of a doctor throughout the transfusion, as Pierce et al. say. In considering the possibility of "overloading" they remark that "with patients in shock due to blood loss this danger does not exist at first, but once approximate replacement has been obtained and blood pressures are near the patient's normal, care must be exercised in continuing transfusions." A most important factor, which they do not mention, is the previous state of health of the patient. Rapid restoration of a depleted blood-volume is one thing in a previously healthy and robust adult, but quite another in a person who has been ill for months or years. Unless there has been adequate preoperative correction of such abnormalities as anæmia —whose effect on the heart in relation to transfusion has been described by Sharpey-Schafer[6]—even transfusions given at the more conservative rates carry some risk of "overloading." Another point which must be seriously considered is the possibility of defects developing in reducing valves on oxygen cylinders used to control the inflow of oxygen to the transfusion bottle. Such a defect might be quickly fatal.

The value of ultra-rapid transfusion must be proved by further careful observation before an opinion can be expressed on the need to use it. Unless it is performed by skilled and experienced operators, aware of its potential dangers, its adoption might well be followed by an increase in the number of transfusion fatalities. Often a sufficiently rapid inflow of blood can be obtained by far simpler and safer methods, such as the use of a 24/10 gauge needle in place of the usual 15/10 gauge needle.

END OF AGENISED FLOUR

SINCE Mellanby[7] announced three years ago that agenised flour can produce hysteria in dogs, and somewhat similar symptoms in the rabbit and the ferret, intensive experiments have been made both here[8] and in the U.S.A. to find out whether it has any harmful effects on man. Meanwhile, however, the U.S. and Canadian governments have prohibited its use in favour of another flour improver, chlorine dioxide. In this country a committee was set up, under the chairmanship of Sir Wilson Jameson and including representatives of the Ministries of Health and Food, the Medical Research Council, and the milling industry, to consider the whole problem and advise on the steps to be taken. According to a statement on another page (227), the committee finds no evidence whatever that the agenised flour is harmful to man, but it recommends that the agene process should be replaced by treatment with chlorine dioxide as soon as the necessary equipment can be imported from the United States, presumably the only source of supplies. This recommendation has been accepted by the Ministries of Food and Health and by the milling industry.

Assuming that flour improvers are essential if we are to get the type of bread to which we are accustomed —and the committee accepts that assumption—the decision to follow the North American example was perhaps inevitable. Nevertheless there is an obvious need for concentrated research to find a biological improver or other form of treatment which by its very nature would be beyond criticism. Chlorine dioxide has the advantage over agene that even in quantities greatly in excess of the normal treatment of 25–30 p.p.m. it produces no toxic symptoms in dogs or other animals. The toxicity of agenised flour to dogs must have created disquiet in many minds, and Sir Wilson Jameson's committee was wise to stress twice in its statement that there is no evidence that it is harmful to man. Oddly enough, two earlier public statements—the first in the B.B.C. news bulletins on Jan. 25, based on the Medical Research Council report for 1945–48 which was issued that day, and the other by Sir Edward Mellanby in a broadcast on Jan. 27—were not so definite.

Presumably the agene controversy in its practical implications is now ended, but the research which it inspired should make useful additions to pharmacological knowledge. In September, 1949, Moran and his colleagues[9] at the Cereals Research Station, St. Albans, announced the isolation of a crystalline toxic factor from agenised zein. The same team have since shown[10] that the factor is a new but relatively simple derivative of methionine—$C_5H_{12}N_2SO_3$—with the additional NH and O probably attached to the S atom. Furthermore, they point out that such a molecule can exist in isomeric

Annotations

TO BURP OR NOT TO BURP?

THERE is something to be said for a short word to convey the meaning of the phrase "bringing up the wind" as applied to the technical side of infant feeding. In the U.S.A. babies are "burped" during and at the end of feeds; and this somehow conveys a short, snappy sort of drill in contrast to the half-hearted stroking of the lower dorsal region which often seems to be the usual contribution of the average nurse or mother to a baby's postprandial comfort. Dr. Joan Tanner, in a letter on p. 230, speaks of her own experiences as a mother and is probably not far off the mark when she states that "wind" is the cause of many of the feeding difficulties of infancy. Air-swallowing is an inevitable accompaniment of liquid refreshment. In the early days of lactation the infant left too long at an only partially functioning breast gulps down more air than milk, and if not taught at this early stage the trick of bringing up the wind will develop a habit of discomfort and refusal to take enough milk when more is available, as Dr. Tanner recounts.

Exactly what this trick consists in is not easy to describe. It must entail some relaxation of the cardia and perhaps a flick of the diaphragm to give the cardiac end of the stomach the chance to expel the air-bubble there. Clearly the baby must be held upright. After this details seem to vary. The object must surely be to give a sudden squeeze to the distended stomach. With one hand or perhaps the shoulder in the epigastrium, the other hand bangs the back on the left side. This should almost certainly be done two or three times during a feed as well as at the end. At first sight the stroking-of-the-back method would seem to have little to support it, but farmers maintain that when choosing a calf at the market, passage of a walking-stick along the animal's spine produces a reflex passage of a stool which can be inspected to exclude an intestinal infection in the prospective purchase. If such a reflex in fact exists, it might conceivably be found in babies, working in the other direction so to speak. Animal studies might throw light on this and indeed on other aspects of the problem of wind. Do suckling animals also swallow air? Do they bring it up without training? It is perhaps significant that the common position for breast-feeding in the human race, at any rate among white peoples, is with the baby on his back and the head to some extent flexed on the body, whereas in the animal kingdom the animal either stands or lies prone with the head well extended. Does this prevent air-swallowing? African mothers often feed their babies with the infant lying parallel, the head in the mother's axilla, and the breast given by the mother slightly rolling over towards the baby. In this position is as much air swallowed as in the more usual European and American method of holding the baby? X-ray studies of the gas-bubble in animals and in human babies fed in various positions might help to answer these questions. Air-swallowing is certainly worse with underfeeding on the breast, and less troublesome with bottle-feeding than with breast-feeding. This explains why discomfort after feeds often disappears when the breast-fed baby is weaned on to a bottle—with the false deduction that cow's milk is more digestible for a particular baby than mother's milk.

Dr. Tanner has done a useful service in calling attention to an important part of management of infant-feeding. If discomfort can be prevented, breast-feeding obviously will proceed more smoothly and less weaning in the early months might result from greater care over burping. If the psychologists are right who attribute aggression in later life to difficulties at the breast, then the question of burping is important in national and international affairs. A campaign to study it seems overdue.

THERAPEUTIC USES OF RADIO-ISOTOPES

THE great interest being taken in the use of active isotopes in this country was illustrated by crowded meeting at the Royal Society of Me (reported on p. 212) to hear various workers di their experiences in the last two years. It seems clear the essential coöperation between clinician and phy has been achieved and that the need to go slowly, m taining the objective view of the scientist, has realised.

The two main applications of isotopes in medi are as tracers and as producers of therapeutic radiat Tracer methods are used in research and diagnosis, when therapy is proposed its accuracy may also depend tracer techniques. Dr. Ralston Paterson pointed out th the principles involved in the treatment of thyroid canc with radioactive iodine are new and differ considerabl from those of the standard methods of radiotherap When the radioactive isotope I^{131} is ingested, like ordinary iodine it enters the blood-stream and is then selectively absorbed by the thyroid. In the thyroid the isotope goes through the usual process of conversion into thyroxine and secretion into the colloid in the acini, and during this period it is constantly irradiating the cells in and near which it lies. This irradiation may be completely destructive of all functioning tissue. Such radiation of the tissue from within is completely different from that obtained by placing radium or radioactive cobalt into holes in living structures or by irradiating the patient from outside, but the mechanism of absorption of electromagnetic radiation and of beta particles is the same. Research has been necessary to find out how far the established principles of protection from radiation, tissue tolerance, and calculated dosage can be applied to the absorption irradiation.

Cancer of the thyroid is now being treated with I^{131} in Manchester and Sheffield, and at the Royal Cancer Hospital in London; but, since selective absorption is only possible in functional thyroid tissue, only a small proportion of these cases will respond to the treatment. Out of 17 cases of thyroid cancer examined by tracer doses of I^{131} in Manchester, Dr. H. C. Warrington told the meeting only 2 were found to have tumours which concentrated iodine, and both were metastases. Once it has been proved that the tumour absorbs iodine it becomes necessary to eliminate the thyroid, because normal thyroid tissue will segregate most of the available iodine. The aim then is to produce a myxœdematous patient whose need for thyroxine stimulates the metastases derived from thyroid tissue to segregate more iodine, so that when the isotope is presented to them they will destroy themselves. The thyroid is best removed surgically, but if this is impossible a radio-elimination can be carried out probably by a single "therapeutic drink" of I^{131}. Thereafter further high doses must probably be given, because only one part of the tumour or one metastasis may be functional at any one time, so each must be destroyed singly. The therapeutic drink consists of 60–70 mC of radio-iodine in water, and it has very little systemic effect. The other important use of this isotope is in the treatment of thyrotoxicosis. The possibilities of the method are being carefully investigated at Sheffield, and Dr. A. G. Macgregor emphasised the value of estimations of the level of I^{131} in the plasma 48 hours after a dose in distinguishing between the various thyroid disorders.

The therapeutic uses of other radioactive isotopes are also being explored. Radioactive phosphorus has already proved valuable in polycythæmia and leukæmia, and emitters such as radiosodium, which emit beta and gamma rays, have been used for intracavitary treatment of bladder cancers. In the future it may be possible to find ways of incorporating radioactive elements in substances which are selectively absorbed in tumours.

Public Health

SCHEME WHICH HAS SUCCESSFULLY EDUCED A SANATORIUM WAITING-LIST

N. Wynn-Williams
M.B. Lond.
HYSICIAN TO THE BEDFORD CHEST CLINIC

J. Brian Shaw
M.B. Belf., D.P.H.
PHYSICIAN TO THE LUTON CHEST CLINIC

W. E. Mashiter
M.A., M.D. Camb.
MEDICAL SUPERINTENDENT OF THE BEDFORDSHIRE SANATORIUM

om the Service of the North West Metropolitan Regional Hospital Board

Sanatorium beds throughout England are lying empty cause of the shortage of nurses, and large numbers of tients who are suffering from pulmonary tuberculosis e in need of institutional treatment. Waiting-lists in ese circumstances are very long, and even cases that e still curable and in need of collapse therapy have, in ost parts of the country, to wait for six months or more obtain admission. Often those not requiring active eatment cannot obtain admission to an institution at l. This has three major disadvantages: in many cases e disease process spreads; the period of disability may e lengthened, and economic waste thereby increased, by he delay in starting treatment; and infection may e needlessly disseminated. Thus any suggestion that night shorten the period of waiting for sanatorium reatment is worthy of consideration.

An important contribution to the problem of disposal f cases needing collapse therapy has been made, over he last few years, by the great extension of domiciliary reatment—not a new method but the much more general se of an old one. Briefly, domiciliary collapse therapy consists in instituting artificial pneumothorax or pneumoperitoneum in the patient's own home and in taking him to a chest clinic, when well enough, for the necessary radiological examination. This is followed by admission to a sanatorium for further constitutional or other treatment, if necessary.

Two main methods of approach have been described:

(1) Heller (1949) starts collapse therapy in the patient's own home, reserving hospital beds for the division of adhesions. For all other operations, notably phrenic crush and bronchoscopy, the patients attend as outpatients at the hospital.

(2) MacLean and Gemmill (1948) induce artificial pneumothorax in hospital, keeping the patient for an average of four days. They do not describe their facilities, but apparently only 3 out of 150 cases had adhesions divided. This would not appear to be adequate treatment by modern standards. Of the last 100 successful artificial pneumothorax cases induced at the Bedfordshire Sanatorium 97 were thoracoscoped, and adhesions were found in all but 2 cases.

None of these authors recommend their procedures except for patients unable to obtain admission to sanatorium within a reasonable time.

The Bedfordshire Scheme

Our object is to describe an experiment which has been operating during the year 1949, with the dual purpose of shortening the waiting time before admission to sanatorium and giving the patient instruction in his illness at an early stage.

The area.—The population of Bedfordshire is just short of 300,000. The industrial town of Luton has a population of 107,000. The remainder is scattered among small country or rural communities with the exception of the county town, which contains 60,000 persons. Bedford is mainly residential although it contains an industrial minority of perhaps a third. The County Medical Officer recorded a mortality-rate of 0·34 per 1000 for pulmonary tuberculosis in 1948, with 100 actual deaths from this cause. Housing and living conditions are taken to be about average for the country and, of course, better than in the crowded areas of large cities.

The area is served by two chest clinics, one at Bedford with 8 hospital beds and one at Luton with 10 hospital beds. The Bedfordshire Sanatorium has 72 beds, of which 64 are allocated to the county. The medical staff consists of a chest physician for each clinic, a medical superintendent for the sanatorium, and an assistant chest physician shared by all three. Three health visitors are attached to each clinic. Latterly it has been necessary to appoint an outpatient sister to cope with the increased volume of work. The sanatorium has a nursing staff of a matron, five sisters, two staff nurses, two assistant nurses, and three ward orderlies. The ratio of nurses (S.R.N., T.A., and S.E.A.N.) to patients is approximately 1 : 6·5.

The success of the scheme depends: first, on the allocation of sanatorium beds to the clinic physicians, and the choice of a selected group of patients for these beds, as well as a general clinic organisation able to manage them after discharge at a very early stage of treatment; secondly, on the close liaison between the clinic physicians and the medical superintendent, to ensure a rapid turnover of suitable cases; finally, on the ability of the chest clinic to deal with a large group of patients not selected for institutional treatment. This scheme was partially operating in Bedfordshire for many months before January, 1949. For this reason the waiting-list at the beginning of that year did not show as grim a picture as it did in most parts of the country.

ALLOCATION OF BEDS

Late in 1948 a proportion of beds in the Bedfordshire Sanatorium were allocated by order of the North West Metropolitan Regional Hospital Board to each of the two chest clinics, on a population basis. This lead was encouraging; and by arrangement with the medical superintendent of the sanatorium the remainder of the beds were allocated to each chest clinic in the same proportion as that suggested by the region. In this way the central waiting-list was removed and each clinic became responsible for all admissions to its own allocated beds, which remained, of course, under the clinical and administrative care of the medical superintendent as before.

CASE SELECTION

Patients attending a chest clinic can be divided conveniently into five classes:

(1) Those under observation as regards activity or diagnosis.
(2) Those considered suitable for collapse therapy.
(3) Those unsuitable for collapse therapy owing to advanced disease, age, or some other reason.
(4) Emergencies.
(5) Those suitable for and awaiting surgery.

The first class must be treated as outpatients except in unusual cases, where admission to a chest hospital or unit (not a sanatorium) may be needed for ultimate diagnosis. This should not often be necessary, for most investigations can be performed on outpatients—as, for example, gastric lavage, laryngeal swabbing, tomography, bronchoscopy, and bronchography. The main resources of the sanatorium were concentrated on the second class, which is in line with the growing practice elsewhere in this country. Apart from those who would profit by training in the management of their disease, patients suitable for collapse therapy probably form the only large group of tuberculous patients capable of benefiting from a short period in a sanatorium. Simmonds and Martin (1948) seem to have shown the value of collapse therapy in prolonging life. We thought that admission to sanatorium as early as possible for the initiation of collapse therapy was more valuable than later admission, after domiciliary collapse, for the following reasons:

1. The final assessment of a case and the full investigations necessary can be performed more easily in the surroundings of an institution than in the rush of a chest clinic.

forms which may differ in biological activity. There is also another consideration; with such a molecule added methionine as such would be expected to suppress any toxic effect, and Heathcote,[11] working in the St. Albans laboratories, has in fact shown this to be the case with the bacterium *Leuconostoc mesenteroides* P 60. A similar mechanism may be at work in the higher animals.

MARRIAGE IN OUR DAY

IMPRESSED by the growing number of marriages which fail, the Society of Friends, in 1947, appointed a commission, with fourteen members, to study causes and possible remedies. The medical members were Dr. Mildred Creak, Dr. Cynthia Harris, Dr. Maeve Marwick, and Dr. Kenneth Southall.

In a liberal report[12] the commission note that refusal to tolerate a marriage regarded as a failure is, in one way, "a mark of healthy idealism and, as such, shows much promise. Many people are aiming high in marriage and are refusing to tolerate a second-best." This is qualified by the reflection that such an attitude may lead to disbelief in the permanence of the marriage relationship. First in their list of causes of failure the commission put the fading of our religious background and a decline in standards of personal truth and honesty. They give the next place to current social conditions, dwelling on our lost sense of security. Moreover shared local life has disappeared in many places; people living in large cities and dormitory towns feel they have no roots in their community, and hence no responsibility for it—and such an attitude may well spread to the marriage relationship. Housing shortages mean lack of privacy. The difficult personal adjustments of the newly married may have to be made in the society of other members of their families: "The 'mother-in-law problem' becomes even more acute when the parties concerned are sharing the same kitchen sink." Too much sexual stimulation by poor films, books, and advertisements; too few outlets and creative opportunities; too much social drinking, especially among girls; the breakdown of parental control; the misuse of contraceptive knowledge; the disruption of family life during the war; the old-fashioned habit of regarding a wife as a possession—all these have their bearing on the present picture. Young people are not taught what marriage will require of them in personal relations, and many are ignorant and selfish in their approach to the sexual function. Few are trained in home-making and parenthood, and many enter marriage for inadequate reasons. Moreover, "emotional and personal maturity are needed to make a really fine marriage." Many of those who marry cannot face the demands of a completely adult relationship—though even this, the commission affirm, is not beyond remedy. The engaged couple who reach a point at which they feel physical expression of their love to be essential should forthwith marry, the commission consider, even if it means a hard life, many sacrifices, and the postponement of childbearing. Those who hesitate to commit themselves to this step should examine their motives more closely. The question of divorce does not as a rule arise for those whose marriage is an expression of a Christian way of life; but it is human to fail, and where the nature of the difficulties are such as to drive the couple apart in bitterness, the commission believe there can be little reason for keeping within the bonds of legal marriage two people for whom no spiritual marriage exists.

As a preventive of this and other types of failure, they advise sex education which begins with a tranquil acceptance by the parents of the child's curiosity about his own body and the process of birth. His questions should be answered easily and naturally, but he should be told, at every stage, only what he asks. He will in any case learn much from harmonious relations between the parents. Children and young people should be encouraged in creative pleasures, enjoyed at home—hobbies, music, play-reading, and the like. Young people should be prepared for marriage as a growing, creative relationship, an adventure requiring much hard work and understanding. Neighbourliness should be fostered; and the social services should be directed less to supplying specific needs of mother and child than to improving the status of the family as an economic unit. The commission end, where they began, with the belief that a religious background makes for greater stability in home life. They have done their work with wisdom and charity, as well aware of half-tones as they are of black and white. Even a wayward generation living in a troubled time should be able to accept their guidance, if they are willing to accept any guidance at all.

AN ATOMIC GARDEN

ONE of the radioactive isotopes of carbon, C^{14}, has a half-life of 5100 years; and from this isotope a relatively stable carbon dioxide can be made. Plants grown in an atmosphere containing this radioactive carbon dioxide would contain radioactive carbon atoms; and the "marked" foods and drugs from these plants could be used for metabolism studies in animals. This theoretical possibility has been put into practical effect at the Argonne National Laboratory, near Chicago; and the *New York Times*[1] has described a visit, arranged by the United States Atomic Energy Commission, to the Argonne Atomic Garden. The plants growing there will not differ visibly from normal plants; but if an appropriate detector is brought near to them, or their leaves or stems, it will signal the fact that they contain a radioactive substance emitting β-rays. The garden must be carefully guarded, and it is perhaps as well that C^{14} emits only β-rays of relatively low intensity and not the more lethal γ-ray; otherwise the poisoned apple of the fairy stories would take a back place and "the gardener in white" truly herald death. Even as it is, a whole new world of possibilities is opened to our writers of detective fiction.

Plants being grown in the garden for pharmacological studies include opium poppy for radioactive morphine, manila hemp for radioactive marihuana, foxglove for radioactive digitalis, belladonna for radioactive atropine, and hyoscyamus for radioactive scopolamine. Other plants being raised are tobacco for nicotine studies, sugar-beet for studying carbohydrate metabolism, alfalfa which will be fed to animals from whose pancreas it is hoped to obtain radioactive insulin, and buckwheat for radioactive rutin. In addition, algæ and moulds are being grown. The algæ are a convenient source of fats, carbohydrates, and proteins, which will be traced in their metabolic journeys. It is proposed to grow *Streptomyces griseus* in this atmosphere and see whether radioactive streptomycin can be obtained from the mould; by adding a radioactive cobalt isotope to the medium it may be possible to prepare radioactive vitamin B_{12} and so help to discover the site of this anti-anæmic agent's activity.

If this technique succeeds, the results are likely to raise as many questions as they answer; but at least we should have a better idea of where drugs go when we give them, and what path food substances follow after absorption.

ON GOING ABROAD

NOW and again travellers find themselves in trouble when arriving in other lands, especially in the tropics, because they are not carrying the necessary certificates of vaccination or inoculation. How these difficulties may be obviated is explained on p. 224 in a note from the Ministry of Health.

---

[11] Heathcote, J. G. *Lancet*, 1949, ii, 1130.

[12] The Marriage Relationship. London: The Society of Friends, Friends House, Euston Road, N.W.1. 1950. Pp. 27. 9*d.*

[1] *New York Times*, Dec. 15, 1948.

dfordshire at any time during the year 1949. It may refore be reckoned that we have had 99·25 beds at r disposal throughout the year. The number of deaths e to pulmonary tuberculosis in the area during 1948 s 100, and hence we have had available about, or ghtly less than, one bed per death.

Table I divides all cases admitted to the 82 beds in dfordshire during each quarter of 1949 into two sses, those recommended as suitable for collapse erapy and those unsuitable for collapse therapy. By llapse therapy we have meant those thought suitable r artificial pneumothorax or pneumoperitoneum and renic crush on the date of recommendation. Not all dmitted as suitable have actually had this form of eatment, and some of those admitted as unsuitable ave ultimately been judged as eligible. The number each class as well as the average time in days spent on e waiting-list was noted, the waiting time being lculated from the date of recommendation from the linic to the date of admission to one of the 82 available eds. The time spent in hospital by cases discharged uring the same quarters was tabulated, and also the verage waiting time and days of treatment of both lasses combined.

Table II combines the figures for the four individual quarters. It can be seen from table I that by the fourth quarter of 1949, the waiting-list for tuberculous patients as judged by normal standards of today, had become nominal and was often accounted for by the necessary arrangements for discharging one patient in order to admit another. The encouraging position had been attained in which patients, especially females, were sometimes being discharged when they had been graded up for more than two hours.

Discussion

A number of objections can immediately be raised in relation to such a scheme. Perhaps the most important is the poor equipment and accommodation to be found at many chest clinics. This inadequacy can be overcome in a number of ways. Mobile chest clinics with an X-ray screening set have been recommended for rural districts by Hoffstaedt (1949), to be used in conjunction with existing clinics without X-ray facilities. Mobile clinics, though perhaps useful in very scattered areas, have obvious disadvantages, one of the most important being the lack of means to take films. They are also unnecessary, in our opinion, where clinics exist, since these can, in a very few months, be modified and equipped with cheap X-ray apparatus capable of taking films as well as screening—as has been shown in the scattered North Buckinghamshire area (*Tubercle* 1949). It may further be contended that except in areas centred in a town or hospital of some size, there is great difficulty in assessing cases, both before and after institutional treatment. This difficulty can be overcome if transport is available and if the nearest chest centre is willing to arrange the investigation of cases on an outpatient basis. In fact this is being done already in many areas.

It might also be maintained that, since many chest clinics admit their cases to a number of different sanatoria, liaison between the chest physician and sanatorium superintendent is difficult to maintain and time-consuming. Arrangements can be made, however, for the bulk of patients from a particular clinic to go to a specific and not too distant sanatorium. Again, it may be said that the sanatorium physician will lose some of his interest if he is unable to follow his patients for the major part of their acute illness. This should surely be compensated for by the number of cases in which he can initiate active treatment early in the course of the disease. Furthermore, the sanatorium physician in many cases spends part of his time working in a chest clinic, and hence should be able to follow up his cases more effectively than ever before. It must not be thought that we are of the opinion that the sanatorium physician is less interested in this problem than the clinic physician; but the initiative must come from the clinics, since proper assessment of cases for treatment is their responsibility. They alone have the necessary accurate domiciliary information to pass on to the sanatorium staff who are often misinformed by patients or their relations about the home conditions. It might perhaps be useful if all admission forms were accompanied by a statement about the facilities at the patient's home for nursing, and at what stage of activity it might be suitable to discharge him for domiciliary treatment. The clinic staff should no longer admit cases to hospital for bronchoscopy or phrenic crush; it is not unknown for clinic physicians to recommend cases to the smaller sanatoria for such treatment, when they could have learned by telephone that no surgeon was visiting the sanatorium, perhaps for several weeks. Similarly, cases of incurable tuberculosis are often admitted, when adequate arrangements could have been made for nursing and isolation in the patient's home. Clinic physicians have a tendency to forget patients once they are in an institution; they complain of the long waiting-lists, but how often do they find time to arrange with the sanatorium staff that their cases should be sent out at the earliest moment?

It is urgently necessary to extend the principle that individual clinics should have an appropriate number of beds allocated to them. The chest-clinic physician would then always know how many beds he had at his disposal, and this would act as a direct incentive to use them to the best advantage of his area.

No mention has so far been made of the results of such a limited period of sanatorium treatment upon the prognosis of the individual patient. Beyond asserting that we have not observed any obvious increase in the relapse-rate, we do not feel justified in making any statement after such a short space of time.

TABLE II—TOTAL CASES FOR THE YEAR AS A WHOLE

Admitted	Dis-charged	Av. waiting time (days)	Av. treatment time (days)	Treatment	Admitted	Dis-charged	Av. waiting time (days)	Av. treatment time (days)
183	186	17·3	173·5	Collapse	107	102	18 9	158·3
				Non-collapse	76	84	15·0	192·0

TABLE I—TOTAL CASES, BY QUARTERS OF 1949

Quarter	Admitted	Dis-charged	Av. waiting time (days)	Av. treatment time (days)	Treatment	Admitted	Dis-charged	Av. waiting time (days)	Av. treatment time (days)
1	40	42	28 8	213 9	Collapse	24	24	32 8	211 1
					Non-collapse	16	18	22·7	217 6
2	41	43	23 5	205 6	Collapse	24	26	26·2	155·7
					Non-collapse	17	17	19·8	281 8

					Non-collapse	21	25	11·7	121·4
4	58	54	8·4	150 8	Collapse	36	30	8·1	125·3
					Non-collapse	22	24	8 8	182·7

2. The growing practice of combining, or even prefacing, collapse therapy in the acute case with streptomycin and 'Paramisal sodium' needs careful and unhurried judgment.

3. Radiological control is far more easily undertaken in the sanatorium, where it can be arranged for the patient on strict bed rest without breaking his routine.

4. Any complications arising in the course of treatment can be immediately diagnosed and dealt with by the physician, who is always at hand.

5. Division of adhesions, phrenic crush, or bronchoscopy when needed, can be done at the optimum time.

6. Patients learn the reasons for sanatorium routine early, are instructed in their disease, and realise from seeing others that theirs is not an isolated case. This knowledge is of psychological benefit in many instances.

The third class consists of cases unsuitable for collapse therapy. We no longer recommend these patients for sanatorium treatment if arrangements can be made for them to be isolated and nursed at home.

The fourth class, the emergency, is always admitted at once, generally to the clinic physician's own hospital. This may mean the temporary erection of an extra bed until a case can be transferred to sanatorium. If no sanatorium patient is ready for discharge, the physician admitting an emergency can claim the next vacancy, whether it falls in one of his own beds, or a colleague's.

Those in the fifth class, awaiting major surgery, are kept at home and regularly assessed at monthly intervals as outpatients. They are admitted direct to one of the neighbouring thoracic surgical units. After operation such cases are transferred to the sanatorium as soon as the surgeon thinks it suitable. The week's notice normally given implies that the postoperative case has first call on the next empty bed, for it is considered even more important to clear surgical than medical beds.

THE SELECTED GROUP

The group selected for sanatorium treatment consists of cases from the second and fourth classes, as well as a few of the third class who—for social or other urgent reasons—must be admitted to sanatorium. If all are to enjoy the benefit of early admission for collapse therapy it is clear that patients can only be kept in an institution for a short time. Thus cases must be selected very carefully so as to ensure that, as far as possible, they are admitted only when suitable for immediate collapse treatment. Moreover, they must all be informed that they are getting in quickly because someone else is going home quickly. It is interesting to note how often patients who are loth to enter a sanatorium are even more loth (or the relatives are for them) to return home.

During sanatorium treatment the closest coöperation must be maintained between the clinic physician and the medical superintendent. Our aim has been to return a patient to his home when he is getting up for two hours daily. In practice the routine varies, for sometimes the home conditions are such that he must be capable of a greater degree of activity than this. It is important that patients should be returned home only if it is possible to obtain the amount of rest prescribed for them. The health visitor plays an important part in the team-work required; she will have up-to-date knowledge of the home conditions, and know whether it is desirable to employ home help, or in some cases nursing assistance. Patients are returned home whenever possible even if further sanatorium treatment is likely to be required in the future—as, for example, those with a pneumoperitoneum and phrenic crush awaiting thoracoplasty. Such patients may be discharged when they are still on bed rest only.

This policy of keeping patients for only a short period throws an added strain on the sanatorium staff. The amount of active treatment given per bed is much increased and the nursing staff have to deal with a much higher proportion of bed cases. This may necessitate actual increases in staff.

An efficient ambulance and car service is essential because many patients attending the clinic for refills are unable to get there by public transport except by breaking their prescribed rest, and this must be carefully guarded against. It is unreasonable to expect them to keep to their routine strictly if they have to break it in order to receive treatment. One of the disadvantages of any system which cannot treat the patient for a considerable period in an institution is that a number will not observe the rules laid down for them. It is perhaps surprising to find that such a small number do, in fact, break their prescribed routine. Tactful visiting at odd hours by health visitors undoubtedly can have a beneficial influence, and careful and systematic grading of the patient makes him take a serious view of this aspect of his treatment. Occupational therapy should be linked up with this graduated system.

NON-SELECTED GROUP

Those falling into the first and fifth classes, along with most of class three, make up the non-selected group. Chronic cases and those not recommended for sanatorium treatment are kept under careful supervision. Each of these patients must have a room to himself, and it is essential that a competent health visitor should give instructions on how to avoid spreading infection and on other preventive measures. She will arrange for the boarding-out of children and whatever other services are necessary. The patient who has no relations or who is living in lodgings or where there is overcrowding must be admitted to the sanatorium; and a proportion of beds is always blocked by longer-stay cases of this type. Patients who wish to go to a sanatorium but who do not require active treatment are told that no special measures would be helpful at the time, and that therefore no particular benefit will be obtained by leaving home. In these circumstances, only those who are exceptionally miserable wish to leave their accustomed surroundings. As far as possible monthly home visits are made by the clinic physician, and patients are brought by ambulance for regular radiography, sedimentation-rate tests, and weighing. Streptomycin is given, when indicated, in the patient's home by the district nurse; she has written instructions from the chest physician and is in constant touch with the health visitor. *p*-Aminosalicylic acid is also given, where necessary combined with streptomycin. These patients are also brought to the clinic at monthly intervals for assessment and for blood and urine examinations, as well as for other routine tests. In selected cases phrenic crush and pneumoperitoneum treatment is started on outpatients.

We consider it obligatory not to neglect in any way the patients whom we have advised to remain at home, and especially to review regularly their suitability for further treatment.

FIGURES DURING 1949

The scheme described above has been brought into operation at the Bedforshire Sanatorium, the St. Peter's Hospital, Bedford, and the St. Mary's Hospital, Luton, during 1949. The beds available have numbered 64, 8, and 10 at these three institutions. At all times during this year a number of patients undergoing treatment for pulmonary tuberculosis have been occupying beds outside the county. Some of these have been admitted to hospital for thoracic surgery, and of course the actual number has varied from day to day. We have therefore noted the numbers of beds filled in this way on the last day of each quarter. The four totals—viz., 19, 19, 20, and 11—have been added together and divided by 4. This gives the figure 17·25 which can be taken as a fair average of the beds in use by our patients outside

INDUSTRIAL PNEUMOPATHIES

CONFERENCE IN BELGIUM

HE Belgian Society of Industrial Medicine met at ssels on Dec. 17, under the presidency of Prof. LAMBIN, of Louvain, to discuss non-silicotic industrial umopathies. Once a year this society asks foreign sts to join in its deliberations ; and on this occasion re were delegations from France, Italy, Great Britain, l Holland.

PULMONARY REACTIONS

rof. J. FIRKET (Liége) opened the proceedings with eview of the reactions of pulmonary tissues in non-cotic pneumopathies. Industrial pollution of the air, said, gives rise to acute and to chronic processes. As the acute processes, irritant gases or fumes act only those respiratory surfaces where they become fixed, d whether that point is on the first surface they meet deeper in the alveoli depends on the specific gravity d the solubility of the substance. In the Meuse Valley 1930, fog contaminated by soot on which sulphur oxide had become adsorbed caused an acute outbreak th hundreds of victims, of whom 70 died. In these tients the disturbance was of two types—either) asthma with circulatory collapse, or (b) pulmonary dema with acidosis—and the type depended on the ze of the inhaled soot particles.

Dusts may cause asthma and other allergic phenomena ; xamples are the complex salts of platinum or the ust of the cotton-flower in byssinosis. Exceptionally, nhaling irritant substances may precipitate acute tuberulosis. Such chemical pneumonias as follow on breathing usts of manganese, vanadium, osmium, or beryllium esemble virus pneumonias both clinically and histoogically ; and this raises the question whether the dusts hemselves provoke the disease or whether they activate viruses.

Among chronic processes are the benign pneumoconioses caused by dusts which have no direct noxious action on the cells. (It seems that some vegetable dusts may cause allergic reactions, possibly owing to the fungi with which they are contaminated.) Apparently neither bronchitis nor the epithelial changes which follow on it predispose to such pneumoconioses ; and yet the bronchial epithelium undoubtedly has a protective action. This Professor Firket illustrated by an analysis of the fate of asbestos fibres, which become dangerous only when they reach the alveoli. He followed their phagocytosis by the histiocytes in the alveoli, and their migration into the peribronchial and periarterial lymphatics and to the hilar ganglia. There these macrophages may cause obstruction of the lymph-flow, and after wandering into the fibrous sheaths, die and leave the dusts they carried. Such is the fate of soot, coal-dust, iron-dust, and alumina. Radiopaque substances, including barium and iron, and others which are deposited as calcium phosphates or which produce a fibrous thickening then cause the appearance of reticulation in the X-ray picture.

When this clogging process becomes more severe, particularly about the arterial sheaths, ischæmia or true thrombosis may cause fibrous scars of more or less extensive areas in the lung ; bronchial obstruction then brings about atelectasis or bullous emphysema, ultimately causing dysfunction through loss of pulmonary elasticity and aeration. Then the pneumoconiosis can hardly be called benign any more—though neither tuberculosis nor other infection often complicate the non-silicotic forms.

Berylliosis and chronic asbestosis behave differently. In the former, granulomata develop which resemble Boeck's sarcoid, though they are not identical with it ; in the latter, asbestos bodies are found in the bronchioles, appearing also in the sputum, but not in the hilar ganglia.

It seems that industrial dusts only occasionally cause primary carcinoma of the lung. Radioactive substances (as in the Schneeberg miners) have, however, proved possibly carcinogenic ; so too, are some arsenical dusts ; but apparently not silica. In the case of asbestos the question is unsettled. The great divergence of opinions suggests that stringent criteria should be satisfied before illness is attributed to industrial dusts.

BERYLLIUM

Dr. DONALD HUNTER (London) recalled that in 1935, because of the valuable properties of its alloys, beryllium became an important metal. Its compounds produce two types of industrial poisoning—acute pneumonitis and chronic granulomatosis of the lung. In the acute disease conjunctivitis, pharyngitis, bronchitis, and dermatitis may all occur. The chronic disease is characterised by delayed onset, progressive dyspnœa, severe loss of weight, and granulomata in the lungs and liver. The histology in one case, that of a physicist engaged in research on fluorescent lamps, was demonstrated and shown to be distinct from sarcoidosis. Less than 5% of persons exposed have developed the chronic disease. In the neighbourhood of a factory in the U.S.A. which makes beryllium metal and its alloys, at least 10 cases are known to have occurred in people who had never entered the factory ; the atmosphere concentrations three-quarters of a mile from the factory ranged from 0 01 μg. to 0·1 μg. per c.m. Halophosphates containing no beryllium have now been introduced as phosphors in the fluorescent-lamp industry. In Great Britain beryllium poisoning has been made subject to compensation.

Dr. L. ROCHE (Lyon) reported on pneumopathies observed amongst workers engaged in the production of beryllium metal. The following substances were handled in the process : beryl ore, which is beryllium aluminium silicate ; beryllium fluoride or chloride ; the oxide, sometimes called *glucine* ; and the metal beryllium or glucinium. Two distinct clinical entities occurred, the first amongst workers handling beryllium fluoride or chloride, and the second, more severe, amongst those handling the oxide.

Workers exposed by an accident to sudden massive inhalation of the chloride or fluoride dust showed immediately signs of irritation, with smarting of eyes and nose, and a cough resembling whooping-cough. These symptoms cleared in a few days, but after a latent period lasting some weeks a new picture developed with fever and dyspnœa. Of radiographs of the lung taken at this point, one showed very characteristic miliary opacities, especially well-marked in the lower lobes, and three a less marked reticulonodular appearance ; a further eight radiographs were normal. All these pathological conditions cleared up in a few weeks, though complete recovery took longer in the more severe cases.

Beryllium oxide gave a very fine dust (Policard, measuring it with the electron microscope, showed that over half of the particles were under 0·2 μ). It gave rise to no symptoms of irritation. Dr. Roche had observed two cases of pneumopathy after moderately short but intense exposure to the dust of beryllium oxide. One of these patients, exposed for roughly sixty hours, remained well for the following three weeks. Rapidly progressive dyspnœa then set in, with cyanosis. On auscultation there were diffuse fine râles. Repeated examination of the sputum showed no tubercle bacilli, but radiographs revealed extensive nodulation of moderate density, most evident in the centre of the lung field. The patient, who was treated symptomatically, died ; at necropsy there was massive pneumonia affecting most of both lungs. The second case was exposed less drastically to the dust ; in him the clinical picture was

Finally, we would like to make it clear that this scheme is not offered as more than a temporary solution of the sanatorium-bed problem. If this system were generally adopted it could give the public at large a totally false impression. The great mass of patients still remain at home in need of institutional treatment and of the sanatorium-course, which time and experience have shown to be the best known means of stabilising their disease and preventing a recurrence. The large sanatorium waiting-lists throughout the country are the true indication of bed requirements. It is regrettable indeed that circumstances should force us to make experiments of this type with such a dangerous and infectious disease.

There is little doubt that patients suffering from tuberculosis deserve a higher priority in beds and nursing than patients with many diseases at present admitted relatively quickly to general hospitals. To give tuberculous patients equal opportunities would necessitate considerable reorientation in the allocation of beds throughout the country, and would reduce the number of general medical beds. By way of compensation, the possibilities of domiciliary treatment for many diseases that are not infectious might be more seriously explored. The larger numbers of general physicians and registrars now being appointed should, with their clinical assistants, make it possible to try this plan; while the general practitioner, who now deplores the loss of his more interesting work, would remain in contact with more of his patients, to their mutual benefit.

Summary

Attention is drawn to the length of the waiting-list for admission to sanatorium, and domiciliary collapse-therapy is discussed.

A scheme for early admission to, and rapid discharge from, sanatorium is described, and argued as more suitable under existing conditions than an extension of domiciliary collapse-therapy before admission.

Such a scheme depends particularly on the allocation of a definite number of beds to each chest clinic; an efficient ambulance and sitting car service; close integration between the sanatorium and clinic physicians; very careful selection of cases for admission; and the adoption of every possible means for treating and isolating patients at home who have either had a short period in an institution or who are unlikely to benefit from such treatment.

The figures for the first year of operation are given. These show that in an average area, with a proportion of beds in use that was less than 1 per pulmonary death, the waiting-list was reduced to negligible proportions—the average waiting time for the last trimester of 1949 being 8·4 days.

It is lamentable that such an experiment should be necessary with an infectious disease.

Salmonella in a Necropsy Room

Wormald[1] reports that after necropsy of infected cases, *Salm. paratyphi-B* and were isolated, despite the use of drainage system, from cotton over-gloves, and from flies captured in the room. He recommends that: (1) open drainage systems should be regularly flooded with disinfectant, and (2) flies should be excluded and any gaining access should be destroyed.

Typhoid Fever in London

Six cases of typhoid fever in Walthamstow neighbouring districts in north-east London have traced to a carrier working in a café frequented workers in local factories and casual callers engaged transport. This carrier has been suspended from w in the café. The onset of illness in notified cases wa the latter half of December and the first week in The organism is of Vi-phage type E.1.

International Certificates of Vaccination and Inoculation

The Ministry of Health receive complaints from ti to time that travellers from the United Kingdom fi themselves in difficulty on arrival in other countr (and in some cases have even been placed in quarantin because they are not carrying the necessary certificat of vaccination or inoculation or because their certificat are not on the prescribed international form.

The onus of ascertaining the requirements of th country to be visited rests, of course, on the travelle himself, who should make careful inquiry of his trave agents or the consulate of the country concerned. Th attention of medical practitioners is, however, speciall directed to the following points, observance of wh will materially assist travellers requiring certificates avoid difficulties on their arrival abroad:

Smallpox.—A certificate of vaccination must be on t international form, which the traveller obtains from t travel agents and takes to his doctor. All headings the form should be carefully completed in legible scr Both parts of the form must be completed—the sec part after the result of vaccination has been obser Certificates only become valid fourteen days after vaccination and normally remain in force for three ye

Cholera and Typhus.—Certain countries dem certificates of inoculation against cholera or typ fever, or both. Here again the traveller must obtain appropriate international form and take it to his doc The certificate normally becomes valid six days a completion of the inoculation. In the case of choler generally remains valid for six months, and in the of typhus for not more than twelve months.

Enteric Fever.—Inoculation against typhoid paratyphoid fever is seldom an international requ ment, and no international form is prescribed certificates of inoculation.

To obviate difficulties, the doctor's signature on a certificates which he gives to a traveller proceedi abroad should be authenticated by the town counc urban district council, or rural district council in wh area the doctor lives. The council will do this free charge if the traveller takes or sends the certificate them.

Yellow Fever.—Where inoculation against yellow fe is required, the traveller can obtain it free of charg any one of the approved centres named in the list out in the "notice to travellers" issued at the pass office and travel agencies. The centre will issue necessary certificate on the prescribed internati form. It becomes valid *ten days* after completio inoculation and remains in force for four years.

The Ministry of Health gives the following ad as to the period which should elapse between small vaccination and yellow-fever inoculation:

1. Whenever possible, yellow-fever inoculation sh precede primary vaccination against smallpox.
2. There should be an interval of at least 4 days bet yellow-fever inoculation (when given first) and pri vaccination against smallpox (when given subsequently)
3. If primary vaccination against smallpox is done there should be an interval of 21 days from the date o vaccination before the yellow-fever inoculation is given.
4. Where there is evidence of previous successful vacc tion against smallpox, yellow-fever immunisation, revaccination against smallpox may be carried out at same session, but if time permits yellow-fever immunisa should always precede revaccination by at least 4 days.

stigations included dust-counts and measurements; onstration of asbestos bodies in the sputum; and cal, X-ray, and electrocardiographic examinations. 75 men more especially exposed, 70 were unaffected, howed doubtful symptoms, and 1 was definitely cted. The radiographic picture was not the classical of asbestosis, but suggested a bilateral fibrous erculosis.

)r. U. THIRY (Ghent) described pulmonary sclerosis h chronic bronchitis among workers long employed he textile industries round Ghent. The disorder was silicotic, but infectious, and was linked with very h bacterial counts in the factory atmosphere.

'he following short communications were given: Dr. R. NOT (Namur), "Les affections pulmonaires dans les loitations souterraines de terres plastiques"; Dr. P. NGOUX (Marcinelle), "Recherches sur les risques de umoconiose dans les moulins à scories métallurgiques"; A. UYTDENHOEF (Brussels), "Recherches sur les ques de pneumoconiose dans les centrales électriques"; l Dr. H. BASTENIER (Brussels) "Les pneumoconioses es aux métaux." A full report of the meeting will appear the *Archives Belges de Médecine Sociale*.

AGENE TREATMENT OF FLOUR

A STATEMENT issued last week by the Ministries of ealth and Food recalls that a scientific committee, ıder the chairmanship of Sir Wilson Jameson, chief edical officer of the Ministry of Health, and comprising presentatives of the Ministries of Food and Health, ie Medical Research Council, and the milling industry, as been reviewing the evidence regarding any possible oxic effects of the commonly used flour improver, itrogen trichloride, known as 'Agene.' The reason for his review was the discovery that the feeding of large uantities of flour treated with agene caused severe oxic symptoms (canine hysteria) in dogs and certain ess severe symptoms in a few other animal species —e.g., rabbits.

The committee, says the statement, has been unable o find any evidence that agenised flour is in any way oxic to man; experiments carried out both in this ountry and in the U.S.A. have failed to produce any oxic symptoms, even where heavily treated flour has een fed at a high level. Nevertheless, in view of its leleterious effect on certain animals, the committee has felt that the use of agene should be discontinued.

The committee is, however, satisfied that if a loaf acceptable to the general public is to be produced in this country, some form of "improver" must continue to be used to safeguard its baking qualities. There exists a suitable substitute in the form of chlorine dioxide. Extensive tests have shown that flour treated with this improver, which is used in quantities of less than 30 parts per million, causes no toxic symptoms in either animals or man. The committee, has, therefore, recommended that this improver should be adopted in the United Kingdom in place of agene. This recommendation has been accepted by the Ministries of Food and Health and by the milling industry.

A change in technique which affects over 90% of the flour used in this country cannot be effected overnight. The position is complicated by the fact that the necessary plant and supplies of the new improver have to be secured from the U.S.A. Every effort is, however, being made to accelerate the change, in the execution of which the representatives of the milling industry have given an assurance of their fullest coöperation. Meanwhile, the statement concludes, "the public can be assured that the present methods of treatment of flour, which have been in operation in this country, the United States, and Canada for some twenty-five years, and which include agenisation, have not been proved to be injurious in any way to human health."

In England Now

A Running Commentary by Peripatetic Correspondents

NOSTALGIA is a funny thing. Little did we think, when the four-engines droned constantly overhead, that we should regret their departure from the Station. At that time the thought of them departing never crossed our minds. But since they left, six months ago, something has gone from our day-to-day life as R.A.F. medical officers. It is the excitement that has gone, and, though we did not know it then, we like excitement. I am not saying that we all lived in a continuous state of mania —our systolics only rose the odd 10 mm. when the voice from Flying Control said "flap failure," or "undercart trouble," or "engine cut on take-off," or "coming in with no brake-pressure"—but a sense of tension and urgency was ever-present: for months on end we never went to sleep without wondering whether we should be disturbed, and if disturbed, whether this would be "it."

Of course we *were* disturbed. We lived beside our staff and patients—"on the job" in fact. We had to pass the inpatients on our way to our bedrooms every night, but they were not the disturbers of our rest. It was the pilot with wax in his ears who wanted them syringed at 4 in the morning after his last "lift" for the night; the navigator with a touch of conjunctivitis who wanted some drops for his eye before flying on the "graveyard shift"; the engineer with precordial pain who only needed a few words of reassurance to be able to report for duty at 6 A.M.; and the signaller we had seen that morning who wanted to see us again at 11 P.M. "just to make sure" we still thought he was fit for flying that night. I am afraid we thought them all somewhat inconsiderate then, but we *do* miss them now.

We are developing into bores, first-class. The number of times we stop ourselves saying "Of course, during Plainfare . . ." is only equalled by the times we don't stop ourselves saying "But then, that was while the Lift was on." The change-over has made a great difference to our sick quarters. No longer do the boys come in shivering at 8 in the morning after 15 hours' 'drome duty cramped in an ambulance at the end of the runway. Nor do they have to deal with a milling crowd of airmen waiting for "treatment." "jabs," or "F.F.I.S." They get more supervision, and frequent lectures from semi-reluctant medical officers to prepare them for trade-tests at the end of the month. I wonder if they look back on happier days too?

When we walk along the perimeter track of an evening, thinking of the times when we used to drive everywhere in our *Volkswagen*, we look out over the vast deserted "apron," and four eyes light up on the runway, and with a roar leap into the evening sky, turn, glinting in the setting sun, and disappear again. But it is only a mirage. Nostalgia is a funny thing.

* * *

I have been reading *Gardening without Digging*[1] —a fundamentally immoral book. We have all been brought up to believe that gardeners mustn't be afraid of hard work; but Mr. A. Guest comes along and says the best way to grow bumper crops is to eliminate the work—that is, the digging. The idea is to make a little hole in iron-hard ground, put in a little compost and a seed, and step back quickly or the plants will strike you smartly under the chin. Mr. Guest pins his faith on compost and earthworms. He maintains that applications of compost will allow for the same crop to be grown in the same place year after year, that it is better than farmyard manure (he of course, would *never* consider artificials at all), and that it tends to discourage weeds. He believes that earthworms, who turn up much more freely in the presence of compost, aerate the soil sufficiently; and that digging buries the bacteria—our main allies in fighting plant pests—80% of which are normally found in the top 4 in. of soil. Mr. Guest is also of the opinion that food grown on fertile soil leads to health; and claims that this is corroborated by feeding one lot of rats on grain grown on fertile soil and another lot on grain grown on infertile (in Mr. Guest's meaning of the word) soil. The two kinds of similar but less severe. The radiological lesions cleared completely in about two months, and a year after the onset he was still free from any sequelæ.

---

[1] Doncaster: R. Wigfield. 1949. Pp. 47. 2s.

Prof. A. Policard had performed experimental work of great importance. Inhalation of beryl or beryllium metal proved harmless to animals under the experimental conditions; but inhaling beryllium fluoride caused very rapid death, with intense pulmonary congestion and œdema and very severe lesions of the bronchial mucosa. These early lesions seemed due to the formation of hydrofluoric acid in the pulmonary epithelium. With beryllium oxide the lesions were more delayed, arising about twenty days after exposure and resulting either in pneumonia or in granulomata.

Histological examination of both experimental and clinical material revealed notable proliferation of both the mesenchyma and histiocytes, histiocytic lobular pneumonia, nodular granulomata, and well-marked thickening of the alveolar walls. These accidents all took place in one plant; and very strict precautions should successfully prevent further accidents.

Dr. A. Uytdenhoef (chief medical inspector of factories for Belgium) pointed out that no beryllium metal, nor any of its salts, were manufactured in Belgium. The salts were used as a paste in the making of fluorescent lamps, and no accidents of any kind had been observed amongst such workers in Belgium, nor had they been observed in Sweden. Dr. P. A. van Luyt (Amsterdam) commented that though no accident had as yet occurred in Holland, workers' clothes in fluorescent-lamp factories were shown to be covered with beryllium dust.

The British delegation felt very strongly that since there were effective harmless phosphors for fluorescent lamps, and only a percentage of subjects were susceptible, and that with a latent period, the use of beryllium was unjustified. It was stated that in Belgium, too, beryllium was now being replaced by harmless substitutes.

EFFECT OF IRON-DUST ON THE LUNG

Dr. A. T. Doig (Glasgow) observed that exogenous iron inhaled as dust or smoke is harmless as long as free silica dioxide is absent: workers engaged in soldering, metal-polishing, or the production of iron oxide may, and often do, show reticular or nodular opacities in radiographs of their lungs; but they are fit men who remain at work. This finding is confirmed by the clinical statistical data, pathological findings, and experimental work. If, on the other hand, the iron-dust is coupled with free silicon dioxide, a siderosilicosis ensues with fibrosis of the lung which ultimately disables the worker: such is the fate of hæmatite workers or boiler-scalers. Dr. Doig therefore insists that the reticular or nodular opacities in the radiographs of iron-workers do not signify fibrosis of the lung, and that "pneumoconiosis" is no adequate diagnosis since the benign should be sharply separated from the progressive disabling forms.

WELDERS' DISEASE

Dr. Mignolet (Liége) reported a study of the *maladie des soudeurs.* Taking a group of 100 workers of unspecified trade as controls, he investigated 216 others working with: (*a*) blowpipe, (*b*) oxyacetylene cutting and, (*c*) arc-welding. The first two groups remain clinically fit and show essentially the same incidence of X-ray anomalies of the lung as do the controls. Amongst arc-welders there is a much higher frequency of such abnormalities (60%, compared with 17%), and also in 9·5% of cases limitation of diaphragmatic movement and other disturbances, including acute bronchitis. Moreover, 38 of the 85 men in this group complained of gastro-intestinal symptoms; some of those working with special electrodes had abdominal cramps and vomiting, and 61% were underweight. Dr. Mignolet ascribes these symptoms principally to the sublimation of metals at the point of fusion, especially when electrode contains fluorides; the toxicity is thus portionate to the density of dust at the welding. The whole clinical picture disappeared when p exhaust of fumes was instituted. It appears, t that the main problem arose out of the use of elec containing fluorides, as in welding of stainless (other metal poisons being cadmium and manga and from working in confined spaces without exha precautions. Even in the absence of metallic poiso under such circumstances there is a risk of gassing nitrous oxide produced by the action of the spark the air, and of metal-fume fever when galvanised me is welded.

PULMONARY CARCINOMA

Reporting on lung cancer in nickel, arsenic, an chromate workers, Dr. P. L. Bidstrup (London) stated that between 1921 and 1945 the number of deaths in male attributed to cancer of the lung in England and Wales has increased sixteenfold. This cannot be explained by improved diagnosis, nor by increased opportunity for necropsy examinations. Possibly workers handling nickel, arsenic, and chromium compounds are particularly liable to develop cancer of the respiratory system However, the number of men at risk in each case i small and the errors in sampling may be enormous There is little evidence that exposure to arsenic compound causes lung cancer. Workers engaged in the Mon nickel process frequently develop cancer of the ethmo or lung, but the carcinogenic factor to which they a exposed is unknown. Figures of the mortality experien of workers in Germany and the U.S.A. suggest that lu cancer occurs from four to sixteen times more commonly i the chromate-producing industry than in other industr groups. Monochromate rather than dichromate may b responsible; for preliminary environmental studies chromate-producing factories in Great Britain indica that the atmosphere contaminant in all parts of th plant is monochromate.

TALC PNEUMOCONIOSIS

Dr. A. I. G. McLaughlin (London) described what is believed to be the first fully proved case of talc pneumoconiosis. Amongst cases described in the past it had often been impossible to exclude asbestos as a possible cause; and, in other series, suggestive radiographs had not been accompanied by any clinical symptoms. His patient, aged 50, had worked since the age of 14 on the same tyre-extruding machine in the same factory. At the age of 12 he had had chorea with consequent heart-disease. He first complained of pain in the right hypochondrium at about 49 years of age, and he died 2 years later. X-ray examination showed generalised nodulation of the lung which could not be distinguished from asbestosis. Dr. McLaughlin studied the macro scopic and histological appearances of the lung and its chemical analysis, and investigated the composition of all the talc used in that factory. The dust in the lung had been analysed by the methods of petrographers and by X-ray crystallography. By these methods asbestos as a causal agent was excluded.

OTHER HAZARDS

Cases of pneumoconiosis in the sulphur and barium industries were reported by Prof. G. Pancheri (Milan). In the sulphur industry workers are exposed to both dusts and fumes with ensuing dyspnœa, cyanosis, bronchitis, emphysema, and even bronchiectasis. The condition is rarely complicated by tuberculosis, and it has sometimes been attributed to fumes rather than dusts. Professor Pancheri showed striking radiographs of nodulation in the lungs of barium workers. Clinically the condition is benign.

From Brussels Dr. J. Clerens presented a report of his experience as doctor to an asbestos works. His *appreciated, a change in the position of the arm* ying the infusion was made. Whenever a suitable in the dorsum of the wrist or forearm was present, was chosen. If a vein in the antecubital area was only choice, the arm was fixed on a padded arm-board he pronated position. In either event both arms e subsequently placed adducted to the patient's side held in place by a wide retaining strap placed under patient's buttocks and over each hand. The tubing the infusion was increased to allow the bottle to be ced conveniently at the foot of the table out of the y of the instrument nurse. Since this procedure was pted we have not been troubled with another case paralysis.

uring 1948, 145 cases, each carrying an infusion ring operation, were treated, with the 4 cases of alysis in the first four months. During 1949, 177 es, each carrying an infusion during operation, were ated without paralysis.

holt, Shipley, Yorkshire. WILLIAMSON J. FINNIE.

SIR,—The articles by Mr. Ewing and Dr. Kiloh raise estions of considerable practical importance. On one it of St. Bartholomew's Hospital during the last urteen months we have had 2 similar cases, which are re recorded briefly.

CASE 1.—A woman, aged 33, underwent appendicec- my, oöphorectomy, and myomectomy in November, 1948. fairly steep Trendelenburg position was maintained with dded shoulder-rests. The left arm was abducted and ternally rotated on an arm-board. The anæsthetic was iopentone, curare, and gas and oxygen.

Postoperatively she had a partial lesion involving all muscles pplied by the left brachial plexus, with sensory impairment cervical segments 5–7. This has improved progressively, ut she still has slight weakness of the long finger flexors d muscles of the thenar eminence. In addition, there is nsiderable functional overlay which renders the hand, from er point of view, practically useless. As she is an embroideress, is is a serious matter.

CASE 2.—A man, aged 43, underwent an operation for ansplantation of ureters and total cystectomy in July, 1949, he anæsthetic being thiopentone, curare, and cyclopropane. ere there was only a slight Trendelenburg tilt, maintained ith shoulder-rests, but the right arm was abducted on a oard.

He developed a lesion involving muscles supplied by the th and 6th cervical segments on the right side. This is now mproving but there is still considerable weakness of elbow- lexion and for this reason he is unable, so far, to resume is occupation of lorry-driving.

Since the last of these cases occurred we have abandoned the use of shoulder-rests, and use instead pelvic ests which support the patient against the iliac crests. hese have been made for some years by Messrs. Allen nd Hanburys, originally I believe for St. Peter's Hospital. The use of these rests does remove one of the two actors responsible for these lesions, but I agree that every ttempt should be made not to abduct an externally otated arm on a board.

St. Bartholomew's Hospital,
London, E.C.1. MAURICE LUNN.

SIR,—In view of the cases reported by Mr. Ewing nd Dr. Kiloh in their excellent articles, I wonder if I nay draw attention to an article written by me last year.[1]

In this article was described and illustrated a method of supporting the patient's arm during operations in the Trendelenburg position where tubocurarine was being used. The elbow is drawn across the patient's chest and anchored to the far side of the table with a strip of adhesive plaster; the hand rests on, or near, the face, and the veins of the wrist and hand are easily accessible for puncture.

I have used this technique, with minor modifications, for two years and have had no trouble. In many cases this arm has been used for a transfusion during operation; and the transfusion can be set up quite easily without disturbing the towels or the surgeon to get at the arm. For the administration of drugs intravenously, a Gordh needle is now most commonly used.

Lincoln. J. CLUTTON-BROCK.

SIR,—I was very interested in Mr. Ewing's article, and heartily endorse his views. I notice he suggests that it may be necessary to devise some method of utilising the iliac crests, &c., as points of pressure in the Trendelenburg position. May I draw attention to the pelvic rests in use at St. Peter's Hospital for Stone, which I feel go a long way towards preventing this complication?

Luton. S. H. C. CLARKE.

SIR,—I am glad that the important articles by Mr. Ewing and Dr. Kiloh received the prominence they deserve in your leading article of the same date. This is a problem which has long needed discussion.

In my own experience, I have had no cases of such injuries following the use of the Trendelenburg position. This is perhaps because I have always insisted that the shoulder-rests, of whatever design, are merely inserted as a precautionary measure, and that the shoulders must not actually touch them. The weight of the patient is taken *by the flexed legs, which are strapped to the dropped leaf* of the table over pads. I admit that theoretically this increases the risk of thrombosis, but in our hospital the incidence of this complication is no higher than elsewhere, whereas our incidence of brachial-plexus injuries is apparently much less.

I believe that the operation of radical mastectomy carries a high risk of this complication, though I can find little reference to it in the literature. My practice in this type of case is to insist that the weight of the arm is taken by a nurse who sits at my side during the operation. The only case of plexus injury I have had was in a case where this precaution was neglected, but the operation was only a local excision.

The other case of this sort that I have had was an Erb's type of palsy following operation for nephrectomy. This I attributed to the neck being overstretched by the removal of a pillow after the operation and while the arm was still attached to the arm-rest.

Another point to which I would draw attention is the importance of never bandaging an arm to a splint for a transfusion with the hand supinated. If anyone doubts the importance of this, let him lie for a few minutes only with his arm abducted at the shoulder and extended at the elbow, and with the wrist supinated. The relief obtained by pronating the wrist is remarkable, and in this position all the veins of the forearm are accessible, including those in the antecubital fossa.

These points are all simple, but I believe they should be brought to the notice of all anæsthetists.

Worthing. F. R. GUSTERSON.

SIR WILLIAM OSLER

SIR,—From the obituary notice last week of the late Dr. A. G. Gibson it would appear that Sir William Osler was appointed regius professor of medicine at Oxford in 1911. For the sake of historical accuracy, on which both these men were very keen, it should be stated that Sir William Osler was appointed in 1904 and arrived at Oxford in 1905.

Between Sir William and Dr. Gibson there were indeed bonds of friendship, admiration, and affection; and it was Dr. Gibson who attended Sir William in his last illness in 1919. P. T. C.

---

[1] *Anæsthesia*, 1949, 4, 141.

grain, incidentally, showed no difference on ordinary analysis. However much this savours of black cats walking widdershins the compost heap at the full moon, most of us would be only too willing to believe that we can grow bigger and better vegetables *and* have our after-dinner nap. Though it should perhaps be mentioned that Mr. Guest seems to base his findings on only a few years of experiment.

* * *

There are various ways of leaving a hospital. Seeing a man leaving the outpatient department of a large London hospital at racing speed the other day reminded me of some dramatic exits I have witnessed in a West African colony.

One patient had symptoms which were alarmingly suggestive of commencing rabies, and he spoke no language known to anyone in the ward. On such occasions a certain male nurse, short and corpulent of form, flat of foot, and piscine of mouth, who spoke twenty different dialects, was always summoned. We had this worthy fetched, and requested him to ask the patient if he had been bitten by a dog. The question was put in all twenty tongues with rising exasperation but no response, and then our interrogator suddenly got down on all fours, barked sharply, and took a snap at the patient's ankle. We never saw the poor fellow again; it was a mere blurred streak that left the ward. His hospital pyjamas were duly written off.

Kwame, the mortuary attendant, had an uncanny flair for nosing out a dying patient, and his ghoulish face peering round a ward door was not a popular sight. Two patients died in a ward one day, and between them was the bed of a deeply concussed patient; nobody seems to have noticed that the bodies removed to the mortuary were from adjacent beds. Not long afterwards Kwame beamingly opened the door of the mortuary for the pathologist, took one look inside and did not wait to hand in his resignation. Whether he actually did clear the eight-foot hospital wall, as rumour says, is not certain, but even the pathologist admits that to see a corpse sitting up and gibbering at him was unnerving.

We had an earthquake in 1939, and among others the male urogenital ward was evacuated. There were three modes of exit: (1) the frankly timid pulled out the catheter and ran; (2) the rather more valorous removed the catheter from its continuation drainage tube and ran with catheter in situ; and (3) the outright heroic undid the attachment of the bottle into which they were draining and marched out grandly with the whole bag of tricks. From all these operations none of our catheters was missing.

I wonder why that man in London was running. To catch a bus? Oh no; this was real terror. Perhaps the Minister himself had caught him malingering.

* * *

Speaking for his confreres on Jan. 21, a member of the M.R.C.P. Faileds Club expressed approval of the new examination arrangements. I presume he has taken into consideration the increased plough-rate (since the alteration). Indeed, it may well be that he regards the higher mortality as a satisfactory feature, an indication that hitherto the Censors have been too lenient and that a nearer approach to justice has now been achieved.

I had predicted this result. I look back over my 20 years' experience as an examiner. I can see that in my earliest days my standard of expectation was almost preposterous: it was well that I had the curbing influence of a senior colleague. It takes time to develop a sense of proportion and you have to arrive at senescence to realise its value. The new arrangement will have the advantage of educating inexperienced junior examiners, but the price must be paid. And so some of the aspirants to M.R.C.P. who fall by the way may preen themselves on their altruism, that their sacrifice was *pro bono publico*.

* * *

I feel sure that readers will be glad to hear that my lucky friend of Jan. 28, who had seen the same patient with syringomyelia at three different examinations, has recently had a bash at the M.R.C.P., and one of his short cases was the same syringomyelic patient yet again, the fourth time in all. Alas, even this gift from the gods did not avail.

Letters to the Editor

CONTROL OF TUBERCULOSIS

SIR,—In the interesting correspondence on this subject no mention has been made of the place of village settlements or of how they might be used to relieve the present difficulties over sanatorium waiting-lists.

Local authorities have powers under section 28 of the National Health Service Act to provide aftercare. They have also powers to use in any other region facilities not available in their own. By arrangements with regional boards, patients could be transferred to village settlements when they are fit to be up and to take moderate exercise. All modern treatments can be carried on in those settlements, which are built round treatment blocks. The patients so transferred would have definite advantages. Once they are fit to undertake sedentary work for three hours daily they can receive the grants available through the Ministry of Labour's generous adaptation of the Disabled Persons' Employment Act. They would be refitted for return to their own employment, or trained for work more suitable to their disability and thereby become self-supporting within the settlements or in outside industry.

At the moment Papworth could take eighty such patients, and with added hostel accommodation could take up to two hundred more workers in its industries. By the autumn Enham-Alamein village settlement will have a hostel for fifty patients; this hostel is capable of extension up to three hundred beds. Other established settlements could make similar arrangements.

This scheme as outlined does of course require contributions from the local authority when the patient is fit to work five hours daily, at which stage he is no longer the responsibility of the regional board. This is surely a small price to pay for the greater use of our present sanatorium beds. It should not be difficult for the Ministries of Health and Labour to arrange details acceptable to regional boards, local authorities, and the managements of settlements.

Papworth Village Settlement. RICHARD R. TRAIL.

POSTOPERATIVE PARALYSIS IN THE UPPER EXTREMITY

SIR,—Your leading article of Jan. 21 and the articles by Mr. Ewing and Dr. Kiloh were of great interest to me. I would like to congratulate them on their excellent description of the mechanism involved, and to endorse their views on the prevention of this distressing postoperative complication.

During the first four months of 1948 I was worried at the apparent frequency of brachial paralysis following abdominal, pelvic, and major vaginal and perineal operations for which I anæsthetised the patients.

All were given curare or a curariform drug and had a glucose-saline infusion set up in the arm subsequently paralysed. The arm, at operation, was placed in the abducted, extended, and externally rotated position on an arm-board tucked under the mattress, or on a padded metal arm-table attached on a swivel to the operation-table. The patients were tilted very steeply—in a 45° tilt Trendelenburg position for the abdominal cases, and a 20° tilt Trendelenburg position for the vaginal and perineal cases.

During this period there were 4 cases of brachial paralysis. Of these, 3 were mild cases in which the most distressing complaint—persisting for about three weeks postoperatively—was inability to hold in the fingers, for any length of time, a cup or a pen. The 4th case was a serious complete brachial-paralysis lesion which did not clear up for four months.

When the connexion between these cases and the position of the arm in the steep Trendelenburg position believe that, by giving a mother sufficient practical p in the first few days of the baby's life, much needless ry and anxiety can be avoided, and the mother bled to take that responsibility towards the baby ich is her right and privilege.

ondon, W.C.1. JOAN TANNER.

APPROACH TO THE UPPER THORACIC SYMPATHETIC GANGLIA

SIR,—Your issue of Dec. 17 contained a letter from . Atkins on the peraxillary approach to the stellate d upper thoracic sympathetic ganglia.

I was very interested to see that Mr. Atkins has already de use of this approach eight times and found it of nsiderable help. Although it is perfectly correct that uggested the operation to Mr. Atkins during my visit London, I should like to emphasise that Dr. W. hulze was instrumental in devising this operation while was my registrar at Groote Schuur Hospital. At e time when Mr. Atkins's letter appeared, Dr. Schulze d I were engaged in preparing an account of the opera- ve procedure. This account was delayed partly by my sit to England but mainly because we wished to obtain ore experience with this approach before publishing d recommending it.

Actually, the peraxillary approach is a modification the transthoracic approach which we reported in 44[1] and which has the disadvantage of causing a ther unsightly scar. The peraxillary approach has efinite advantages, one of these being that the sympa- etic chain from the stellate ganglion down to D5 and 6 n be removed with the greatest of certainty and the ast possible trauma. Mr. Atkins has already pointed it that it is important to remove the third dorsal nglion when sympathectomising the upper extremity, Kirgis and Kuntz[2] have made clear. There is no doubt at the peraxillary approach is less traumatic and more anatomically certain" than the posterior approach; nd the dangers inherent in the anterior approach, such s bleeding from an intercostal vein, can be avoided; nd, if bleeding does occur, it is easily controlled with he peraxillary approach.

We have demonstrated on several occasions that the mpathetic chain may be removed with advantage by he peraxillary approach without actually entering the leural cavity. The incision is the same, but it is easier o strip the pleura from the thoracic cage if a piece of the econd or third rib is removed.

Dr. Schulze and I are hoping to present a full account f this approach in the near future and will be most nterested to hear the results obtained by those who have sed it.

Department of Surgical Research
University of Cape Town.

R. H. GOETZ.

SIR,—Mr. Atkins (Dec. 17 and Jan. 14) has, I think, et a new fashion in describing the technique and dvantages of an operation devised by another surgeon. erhaps this fashion has advantages in that the writer s not handicapped by *amour-propre* and the enthusiasm f an inventor. Examples will come to mind of a surgeon ontinuing to perform an operation merely because is name has been widely connected with it.

It is in this fashion that I would like to draw attention o an approach to the upper thoracic sympathetic anglia demonstrated to me by Mr. Norman Lake, and I believe devised by him. It is a modification of the anterior approach described by Sir James Paterson Ross, in that after division of the scalenus anticus the subclavian artery is cleaned from any surrounding areolar tissue and retracted upwards, and the approach is made between the artery and vein. By this route no arteries are ligated or divided, for no branches come off the inferior surface of the subclavian artery. It is amazing how far the artery can be retracted upwards: I have hesitated to retract the artery only once, and that was in a woman of 64 whose vessels might have been too rigid for this procedure to be safe.

I have performed the operation forty times, and have never failed to reach the 3rd ganglion; and in one case of severe axillary hyperhidrosis I took the 4th ganglion also. At first I divided the trunk below the 3rd thoracic ganglion and all the rami of the 3rd and 2nd ganglion. I avoided dividing the 1st white ramus, to prevent Horner's syndrome, I then anchored the cut end of the trunk to the scalenus anticus. The theory of regeneration of a gap of an inch has, however, strained my credulity, and I now take away the 2nd and 3rd ganglion and the trunk between them. I think that the explanation of so-called regeneration put forward by Boyd and Monro[1] —that it is due to a collateral supply—is more credible, so I no longer displace the trunk.

The advantages of this approach are simplicity, absence of pneumothorax as a rule; benefit, in certain cases from division of the scalenus anticus; and the benefit of the periarterial sympathectomy which results from cleaning and retracting the artery. The only added risk that I know of in this approach between the artery and vein is that one may damage the thoracic duct at the inner corner of the incision. I did this twice in my earlier cases, but there was no apparent ill effect. A pneumothorax may occur, especially if blunt dissection is used to separate Sibson's fascia, as the pleura gives way before the fascia—for this reason sharp dissection is preferable. A darkened theatre and illuminated retractors and a headlight I find helpful. I record with pleasure my gratitude to Mr. Norman Lake for demonstrating the method to me.

Hove, Sussex. H. J. McCURRICH.

INFLUENCE OF HEART-RATE ON CARDIAC OUTPUT

SIR,—Further correspondence gives an opportunity to clear up one or two misconceptions.

The Fick equation for estimation of cardiac output (C.O.) in litres per minute is:

$$\text{C.O.} = \frac{\text{Oxygen uptake in the lungs in c.cm. per min.}}{\text{Arteriovenous oxygen difference in c.cm. per litre.}}$$

Oxygen uptake is measured by a spirometer, the subject breathing *oxygen-enriched air*. This is done at the beginning of the observations; and, since the subject is at complete rest, this figure is taken as the numerator throughout the observations. The validity of this assumption has been checked by similar estimations made at the end of the experiments, which show that the coefficient of variation of this oxygen-uptake estimation is ± 5%. 3 ml. samples of right-heart blood and of arterial blood are shaken in air in the Haldane apparatus and their *oxygen uptake* measured directly. The difference between these figures gives the arteriovenous oxygen difference. Ferricyanide is *not* used. Since the subject is breathing room air at the time of sampling, no difficulties arise from extra dissolved oxygen. The coefficient of variation estimated from pairs of arteriovenous oxygen differences is ± 3·5%. Single estimations of cardiac output may thus have a coefficient of variation of ± 8·5%, but of course this error is reduced by multiple sampling at all critical points of an experiment, which is our habit. None of the reported figures is based on less than two estimations, and three is more usual.

With regard to some of the other points raised, normal subjects with rapid heart-rates from mild anxiety may have very high cardiac outputs, reaching 11–12 litres per minute; while in severe heart-failure the output may

THE HEALTH OF NURSES IN HOSPITAL

SIR,—At last there seems to be a tendency to speak plainly about the long scandal of the exploitation of nurses. Some sentences of Dr. O'Daly's letter in your issue of Jan. 21 should sear the minds of hospital boards or nursing committees. Taking Dr. Court's survey of six hospitals he can think of no other group whose working hours are so long, and considers that quite sufficient to account for the high incidence of tuberculosis among them; he says, *starkly, it is wrong* of hospital authorities to force girls in late adolescence or early adult life to work under such conditions. Present-day authorities will argue that the doctors have always allowed it. Yes, the writing on the wall has been so largely ignored that we have allowed tuberculosis beds to be closed by tens and hundreds rather than face the implications of the quiet stay-out strike. We deserve what we have got. Even now we offer kindness and sympathy where we should be awarding reasonable compensation for the loss of vigorous health or wasted years. Many of us who have followed the ill fortunes of nurse-patients know that fear of anxiety and poverty still deter the sisters and friends of such girls from entering tuberculosis nursing. When our "sympathy" gets to the point of recognising the industrial hazards of the nursing life we may at last begin to stop the rot.

Moor Park, Northwood. ESTHER CARLING.

SIR,—I should like to thank all who have commented on my article,[1] and especially my old mentors, Dr. Brailsford [2] and Professor Stammers.[3] My main purpose was to discover and present the facts about one kind of hospital in the hope that others would complete the picture.

Dr. Hubble,[4] in his well-reasoned letter, took the process a stage further by stressing the inadequacy of a general-practitioner service to meet the special needs of nurses in hospital. I would support his plea, with that of Dr. Greenwood,[5] that this should be the concern of one physician "rather than a series of changing residents." For a physician in a teaching hospital, this continued study of health and sickness in a well-defined community might also have a beneficial effect on his teaching of the undergraduate. I would agree, too, that certain essentials of medical care to be expected from all hospitals might be laid down with precision, but I shrink from defining the process "in detail." I think Dr. Hubble will agree that we must avoid adding to the list of forms requiring automatic and, before long, unthinking completion. If the physician concerned is to maintain a lively interest in the subject, he must be free to initiate what special studies his interests, or the needs of the hospital, require and be free therefore to design the record-card best suited for the purpose.

The question of records is of some importance, and I am very sorry indeed that my paper contained no reference to the sensible card designed by King Edward's Hospital Fund for London, and their wise memorandum on the supervision of nurses' health. The latter needs no commendation from me, and I wish that its suggestions, especially those concerning the precautions which nurses should take with potential cases of tuberculosis, were more widely known.

My attention has also been called to the apparent fall in wastage during training which is now taking place. The index of student nurses, initiated by the General Nursing Council, reveals a wastage-rate for all training schools of 25% between June, 1947, and September, 1949. Although these figures are incomplete, as a number of nurses had not reached the end of their three years' training and the figures from sick children's mental training schools are less favourable, we reasonably hope that this stubborn professional is at last beginning to yield.

It has been hinted, too, that my picture of the incidence of sickness and the quality of health supervision has changed rapidly for the better in the last five years. If this is the case, no-one will be more delighted than I; but with some experience of how practice lags behind precept in this field, I will await the facts. It would, I know, be most encouraging to all who share my concern in this matter if the Medical Research Council or some other suitable body would decide the existence and extent of the risk to health in nursing, and the quality of supervision for which it calls.

The Children's Department,
Royal Victoria Infirmary,
Newcastle upon Tyne.

DONALD COURT.

HISTORY OF WESTMINSTER HOSPITAL

SIR,—The board of governors of Westminster Hospital have commissioned Mr. John Langdon-Davies to write the history of the hospital since its foundation in 1719. It is intended that, apart from recording the hospital's activities, the book shall be a social history of the conditions which brought the voluntary-hospital movement into being at the beginning of the 18th century, and which led to the founding of our hospital.

We should be grateful for the assistance of anyone who possesses documentary or other material useful for the writing of the history, and particularly for any reminiscences or notes about the hospital which past or present members of its medical staff would care to contribute. All original material will be carefully copied and returned.

Information or inquiries in regard to the history should be addressed to me.

Westminster Hospital,
London, S.W.1.

CHARLES M. POWER

FLATULENCE IN INFANCY

SIR,—I have devoted the past year to the care of my infant daughter, and by observation have learned a number of practical details which I believe would be useful to many mothers if more widely known. Mostly these observations concern wind, which is undeniably the cause of many of the feeding difficulties of infancy.

The mother should be instructed to bring up all the baby's wind during the course of each feed, and not only at the end. This is especially important during the early days, when the infant's stomach is relatively small in relation to the volume of its feeds. When the combined volume of milk and air is sufficient to distend the stomach, the infant ceases to suck although he may have taken as little as $^1/_2$ oz. milk. Efforts to force the baby to take more only cause vomiting, unless the wind is first brought up.

This is most effectively done by holding the baby up and patting or stroking firmly over the left lower ribs at the back and side. It must be remembered that the average mother does not know the position of an infant's stomach, and thumps indiscriminately over kidneys, liver, and lungs. Patting over a stomach full of wind elicits a hyper-resonant note which changes so much when the wind is shifted that an intelligent mother or nurse would soon learn to distinguish the "end point." "Splashing" is sometimes noticed when a baby is picked up or its position altered; this should be taken to indicate the presence of wind and calls for similar measures.

It is well known that an infant should be fed comfortably and quietly without hurry or fuss. The same conditions are just as essential when dealing with wind. It is impossible to bring up wind while a baby is crying—in fact, it usually swallows even more air.

that in the insane and in mental defectives tuber- sis runs a very sluggish course, as if in harmony the sluggish faculties of the mind.

hose who opposed the motion thought it was futile ittempt to assess the relative importance of seed soil in the ætiology of tuberculosis. They ignored case-histories of identical twins which suggest t the soil is the predominating factor in the develop- it of tuberculosis. In my view, little more knowledge be gained by further research on the tubercle bacillus ; ecially since observations by the late Dr. Galen— t, in A.D. 80, those who associated with tuberculous ients were more liable than others to contract the ease—have now been confirmed in the Prophit report. ose of us who support the motion realise that our iorance of what constitutes resistance is abysmal. natural immunity we know no more than the ysicians of 1850. Therefore I have said that when ich discovered the tubercle bacillus, he put the clock ck. For this epigram I am regarded as a heretic by ose who cannot see beyond the present bacteriological i in medicine.

Birmingham Mass
Radiography Centre.

HALLIDAY SUTHERLAND.

VITAMIN E

SIR,—In their letter of Jan. 7, Dr. W. E. and Mr. E. V. iute state that we have emphasised the powers of tamin E as a physiological and safe anticoagulant. his conclusion is a most unfortunate misinterpretation f our communication and imputes to us a suggestion hich was neither stated nor implied in our report.[1]

Despite much careful and thoughtful work the rôle f the tocopherols in physiological processes is still bscure. *Conclusions* regarding their function should be rawn only on the basis of the most rigorously proved ibservations. *Speculations* are welcome but should not nasquerade as anything more substantial.

THE SOCIAL ADAPTATION OF INSTITUTION CHILDREN

SIR,—Last week's article by Dr. Bodman and others bases important deductions about the hereditary factor in child maladjustment upon a table of constitutional factors in relatives which merits very close study. The general trend of studies suggesting that the attitudes, and even the apparent intelligence, of institutional children can be environmentally modified does not, of course, rule out the genetic element in maladjustment, but it may lead us to restrict its rôle. One of the problems of assessing family background is the extreme difficulty of getting unbiased information about "good" homes, and on this score the table seems suspect.

Children who are handed over to institutional care bring with them details of delinquency and insanity in the family based on reports by trained or semitrained observers. There is a greatly reduced opportunity for a social "cover-up." The information about the control population in this paper appears to be drawn from sources such as school records based upon interview, and it would be interesting to hear further details of its reliability. Suspicion is strengthened by the fact that the incidence of neurosis and "insanity" in test and control groups show an inverse correlation, while no antisocial individuals are detected in the control group. A certain unavoidable element of selection is likely to be introduced into any series of this kind: testimony that "uncle was a bad lot," or that a relative has been "put away" is freely forthcoming in any case which comes to court, or is investigated by child-welfare organisations: in the "better" home-group, psychoses are readily softened to nerves, and delinquency to "whereabouts unknown." One would like to ask the authors whether, and to what extent, this factor has proved controllable in their series.

Physiology Department,
London Hospital, E.1.

ALEX COMFORT.

ARMY MEDICINE IN THE LATE WAR

SIR,—In discussing the treatment of amœbiasis, Dr. Todd [1] makes the following statement:

> "The difficulties of assessing the value of a remedy for such a disease are very considerable even when it is given alone, and when numerous remedies are given simultaneously are even greater. So far as I know, nobody has yet published the necessary large-scale controlled series in which alternate cases are given a standard combination of remedies and the others this combination plus the preparation to be tested."

Much of the information sought by Dr. Todd is to be found in two papers published by us in 1949.[2,3] In these papers we have recorded the effect of most of the drugs commonly in use in amœbiasis, given singly and in combination to African patients all of whom suffered from acute amœbic dysentery. In all cases diagnosis and progress were checked by serial sigmoidoscopy and by stool examinations. All cases showed: (1) ulceration of the colon; and (2) actively motile *Entamœba histolytica* in stools or scrapings. Most of the series in which each drug or combination of drugs was tested numbered 50. In all, the records of some 600 cases were analysed.

A very brief summary of these results is given below. For the sake of objectivity and brevity, we are recording here only the absolute success and failure rates. The latter is the percentage of patients who still showed ulceration and actively motile amœbæ twenty days after the institution of a test drug. The discrepancy in the percentages is made up of "doubtful" cases in which open but healing ulcers were still present, but which showed no amœbæ in stools or scrapings. Unfortunately these figures give no information of the relapse-rate since follow-up was impossible. They are an indication only of immediate cure and failure rates in African patients with an unusually severe and acute form of the disease. An abbreviated table is set out below:

Series	*Therapy*	*No. of cases*	*Probable success (%)*	*Absolute failure (%)*
A	Emetine gr. 15	50	50	28
B	'Diodoquin' 20 days	50	58	24
C	Emetine gr. 15 and diodoquin	61	74	2
D	Emetine gr. 10 and diodoquin	60	75	2
G	Diodoquin and emetine bismuth iodide gr. 30	50	80	6
H	Emetine gr. 10 and carbarsone 2·5 g. in 10 days	45	58	11
I	Penicillin and 'Sulfasuxidine' for 7 days, followed by emetine gr. 10 and diodoquin	56	95	0
J	Penicillin, sulfasuxidine, emetine gr. 10, and diodoquin simultaneously	49	90	2
K	Sulfasuxidine for one week; emetine and diodoquin simultaneously	49	88	2
L	Penicillin and sulfasuxidine simul- s	11	82	0
P*	20 days	57	54	24
Q*	) units daily for 20 days.	55	46	38
T†	Carbarsone	52	48	42
U†	Emetine bismuth iodide	55	71	26

* In the press. † Not yet published.

In view of Dr. Todd's comments and our results, the following observations are made:

1. Dr. Todd states that it is widely believed that a variety of drugs are complementary. Our figures confirm this. Emetine and diodoquin are better than either alone. Results

fall as low as 2 litres per minute. The cardiovascular endothelium is, of course, different from the lining of the mouth and is completely insensitive, the subject being unaware of any subjective sensation with a catheter in situ. If the catheter tip presses on any point inside the heart, premature beats may be induced; but on slight withdrawal to the middle of the chamber these cease and there is not the slightest disturbance of contractile function.

Remarks on "power" and "performance" are mere verbal quibbling. We try to measure the observable—namely, changes in minute-volume of the circulation and in the degree of venous congestion. We cannot draw any conclusions on the significance of changes in stroke-volume, which is a dependent variable resulting from rate and minute output change. We at least know what we mean by change in minute-output, and restoration of this towards the normal is one reliable guide to clinical improvement.

HEAT CRAMPS

SIR,—With reference to Dr. Ladell's letter of Jan. 21, I think that the adrenal cortex may be involved but not in the almost immediate relief following intravenous medication. This almost instantaneous easement must, I think, be due to an effect on the motor end-plate(s) or nerve-supply of the voluntary-muscle focus.

St. Margaret's Hospital, Epping, Essex.
FRANK MARSH.

PLACEMENT MEDICAL EXAMINATIONS

SIR,—Recent correspondence prompts me to add a further point of view regarding medical examination of applicants for civilian employment.

In the interests of industrial morale and personal contentment, it is most desirable that faithful workers should be confident of their management's ability to find alternative employment for them if they become permanently unfit for their normal work on account of old age, sickness, or injury. It is wrong for a worker to give the best years of his life to his firm and then be thrown out when he ceases to be fully efficient.

In this factory, where most of the men engaged on production are unskilled or semiskilled, and do heavy shift work, the number of jobs available for the aged or infirm is regrettably small. We actually have waiting-lists of our own men who have been recommended by their doctors for light or permanent day work. As long as we continue this policy of filling vacancies in comparatively light unskilled jobs by a process of internal transfer, the only unskilled outsiders we require are those who are capable of heavy shift work; and they must show every sign of remaining fit for this work for years. We wish to avoid requests for transfer on medical grounds within a few months of starting work, because more often than not in such cases we are unable to comply, and the unfortunate employee leaves, to the annoyance of all concerned.

This may explain why some applicants are rejected by the doctor after being approved by non-medical officials. The actual number thus rejected is small, and utterly insignificant compared with the total turned away. At the present moment applicants outnumber vacancies by roughly five to one.

British Insulated Callender's Cables Ltd., Prescot, Lancs.
R. N. WILSON
Assistant Medical Officer.

SIR,—Sometimes a particular instance, rather than generalities, makes it easier to judge a situation more clearly. Would Dr. Todd [1] be happy to be a passenger in a ship in which one of the quartermasters had a visual acuity of 6/36, with a colour-defective navigating o on the bridge with him, and where the chief engineer recently recovered from an attack of hypert encephalopathy? This situation might easily arise anyone who had previously done a particular job, felt himself still to be capable of continuing with it, allowed to do so with no medical "screening." As the individual's personal liberty, it is surely reco that in any society some liberties have to be sac for the well-being of the whole.

EXFOLIATIVE DERMATITIS COMPLICATING STREPTOMYCIN THERAPY

SIR,—I have read with interest the article of Jan. 21 by Dr. Harris and Dr. Walley, and note the similarity between their case and those upon which I have reported.[1]

Since that time a further three cases showing dermatitis, sore tongue, and cheilosis have occurred in this hospital. The incidence of these manifestations of vitamin-B deficiency in this hospital alone is now about 3% of all cases receiving streptomycin. I do not include the skin eruptions, relieved by the administration of 'Benadryl,' which are much more common but of relatively little importance and certainly do not warrant reconsideration of the advisability of continuing streptomycin administration.

The last three cases were rapidly controlled by the administration of 'Benerva Compound,' containing in each tablet 1 mg. of aneurin, 1 mg. of riboflavin, and 15 mg. of nicotinic acid; three tablets were given thrice daily. Since January, 1949, it has been our policy to administer benerva compound or 'Becosym' (Roche) to all patients whether receiving streptomycin therapy or not. No further cases have arisen since then. The reference in my article to the reduction in intestinal organisms by streptomycin administration as an exciting cause of clinical vitamin-B deficiency is shortly to be followed by a more complete report from one of my colleagues.

Harefield Hospital, Middx.

RESISTANCE TO THE TUBERCLE BACILLUS

SIR,—As reported in your last issue the British Tuberculosis Association debated on Jan. 20 the following resolution: "That infection, though necessary, is not the major factor in the prevalence of tuberculosis." For lack of time, I could not say all I would have liked to say in support of the motion, and for this I seek the hospitality of your columns.

Mass radiography discovers individuals who have always enjoyed good health although their lungs are studded with calcified lesions, which might be the result of successive infections rapidly overcome by resistant tissues. Some of these individuals give a history that one or other parent and one or more brothers or sisters died of pulmonary tuberculosis. This raises the question why, after presumably the same exposure to infection, some should survive and others die. Those of us who support the motion would like to know what substance is present or absent in the tissues of those who succumb to tuberculosis. Three years ago a fourth storey was being added to the tuberculosis dispensary at San Sebastian, and the tuberculosis officer told me that in this flat there would be three beds and all the necessary apparatus for investigating the metabolism of tuberculous patients. This seemed a promising line of research. There is also a psychical factor, and most clinicians will agree with Dr. Lionel Houghton who pointed out that anxiety will lower resistance to the tubercle bacillus. There is also the well-established

Obituary

HENRY GORDON CAMPBELL

L.R.C.P.E., L.D.S.

. Gordon Campbell, who died at his home in
n Jan. 17, at the age of 79, was the first occu-
he first chair of dental surgery in Scotland.
ntment was apt to the tradition of his family,
her, Mr. Walter Campbell practised as a dentist
e, and his brother, the late Dr. W. Graham
was dean of the Dental Hospital in Dundee
tart in 1919. On his retirement in 1938 Gordon
succeeded him in that office.

Dundee High School he went to Edinburgh
y, but when he was 19 he broke off his studies
go on the stage in London under the name of
)oune. He also did some journalism, and he
end of Richard Le Gallienne. But this break
essional work was after all only an interlude,
eturned to Edinburgh to finish his studies.
e qualified in medicine and dentistry and settled
e in Dundee. In 1913 he was appointed dental
the Dundee school board and for some years
also dental surgeon to the maternity and
fare clinic.

nder of the Dundee Dental Health Association,
so a former president of the Odonto-Chirurgical
of Scotland and of the Dundee Dental Club.
lental school he lectured in dental anatomy
iology, and he was lecturer in oral hygiene in
e for the diploma in public dentistry conducted
ndrews University. He was appointed to the
dental surgery there when it was founded in
e retired in 1946.

ves a widow and two sons. The elder, Mr. W.
Campbell, is surgeon to the Royal Dundee
y, but like his father and his grandfather he
s a dental qualification.

Appointments

. G. M., B.A., M.D. Camb., M.R.C.P.: consultant physician, aster and Kendal group of hospitals.

). Mc R., M.B. Dubl., D.M.R.D.: radiologist, Bolton and ict group of hospitals.

ERHARD, M.R.C.P.: pathologist, Burnley and district p of hospitals.

G. H. H., M.B. Manc., M.R.C.P.: physician, Ashton, e, and Glossop group of hospitals.

FE, E. W., M.B.E., M.S. Lond., F.R.C.S.: consultant orthoc surgeon, Tunbridge Wells and Hastings group of itals.

. P., M.B. Edin., D.P.M.: deputy superintendent (psychia-), Shelton Hospital, Shrewsbury.

D. J. A., M.B. Lond., D.A.: anæsthetist, Rochdale and ict group of hospitals.

Brown, Jean, M.D. Lond., F.R.C.S., M.R.C.O.G.: consultant trician and gynæcologist, Canterbury and Isle of Thanet.

James, M.D. Belf., M.R.C.P., D.P.H., D.C.H.: physician, h Cheshire group of hospitals.

T, James, M.D. Glasg., F.R.F.P.S., D.P.H.: consultant chest ician, Leicester chest service.

Wilson, Carmichael, B.A., M.B. Dubl.: headquarters deputy director of medical services, Nigeria.

are greatly improved if penicillin and sulfasuxidine are added. Anti-amœbic drugs appear to possess synergistic properties which are a justification of the old blunderbuss treatment.

2. Although imperfect, carbarsone is moderately potent and will produce immediate cure in 48%. Its shortcomings are better judged by the high absolute-failure rate of 42%, which is much higher than that of emetine.

3. Emetine bismuth iodide appears to have a higher success-rate than emetine, but the more objective absolute-failure rate is nearly the same. In series U the patients were treated with powdered emetine bismuth iodide tablets placed in gelatin capsules. In a previous series the unbroken tablets were used with most disappointing results; whole tablets were removed from the bowel at sigmoidoscopy and many more were shown intact radiologically. The clinical results were much worse than in series U and 5 patients died before we appreciated the reason. It is beyond belief that manufacturers continue to supply emetine bismuth iodide pills and that gelatin-coated powders are unobtainable.

4. Dr. Todd states that sulphonamides and penicillin are best reserved for cases whose attacks do not take a favourable course. Many cases of amœbic dysentery are so severe from the onset that both these drugs are of immense value. After all, when given separately and alone they are capable of curing the disease and statistically differ but little from emetine.

5. We have now treated 23 cases with 'Aureomycin.' It is the most potent curative agent which we have yet handled.

6. We have found with serial sigmoidoscopies that a proportion of cases which still have open ulcers at 20 days proceed to complete healing at 27 days or later without further treatment. With the drugs at present in common use we have found that many ulcers take 3–4 weeks to heal.

7. We believe that amœbic dysentery is a serious illness requiring precise diagnosis and coordinated treatment. In view of the time required for healing, forward units are at present unsuitable places for treatment.

8. The sulphonamides alone are capable of rendering patients free of amœbæ.

The normal treatment of bacillary dysentery is with these drugs. If all cases of dysentery, both bacillary and amœbic, were treated in forward units without microscopy, all would be treated with sulphonamides. The result would be a disastrous suppression of the diagnosis of amœbiasis and a consequent rise in the number of chronic undiagnosed cases.

URTICARIA COMPLICATING STREPTOMYCIN THERAPY

SIR,—I was interested to read Captain Lindars's article in your issue of Jan. 21. The following case is somewhat similar to that described by him.

A girl, aged 15 years, with tuberculous meningitis, was started on streptomycin treatment on July 16, 1949. She received forty intrathecal injections of 100 mg. each; and she also had 2 g. intramuscularly each day until Oct. 21, when the dose was reduced to 1 g. daily owing to increasing deafness. This dose was maintained until Jan. 11, when she received her 180th intramuscular dose. The streptomycin was then stopped. She had also been on 'Promizole'—1 g. daily—from Dec. 1. This was continued after the streptomycin was stopped.

On Jan. 16, five days after streptomycin was stopped, she developed a profuse urticarial rash on her body and limbs; and she also complained of diplopia. She had ptosis on the left side and her left pupil was dilated. She vomited once that day.

All drugs were stopped. The rash cleared gradually in three days. The diplopia is still persisting slightly (8 days after the appearance of the rash). Her ptosis is much improved. However she has vomited once daily since the rash appeared. She was afebrile after her intrathecal course was completed on Sept. 21 until Jan. 21. On the 4 days since then her evening temperature has varied between 100° and 101°F.

Cork Fever Hospital and
House of Recovery.

M. J. LYNCH.

THE CAPENER NAIL-PLATE

SIR,—It is true, as stated last week by Mr. C and Mr. Hosford, that many devices (in both one two pieces) have been invented for the fixation of t chanteric fractures. The method is a well proved and not only saves life but also makes easier the of such cases and minimises the duration of h care. Even if Coltart and Hosford are unable to that the method is "invaluable," no doubt they allow that, at any rate, it is *valuable* if it achieves results stated.

The nail-plate to which my name has been is, I think, an improved version of the Neufeld device. If eponymous names are to be used, the two should be joined. Surely, however, it is time that eponyms were discarded. It is given to few to be original. The catalogues of surgical instrument makers are cluttered with illustrations of appliances many of which provide poor memorials to the craftsmen named.

The Princess Elizabeth
Orthopædic Hospital, Exeter.

NORMAN CAPENER.

Medicine and the Law

A Forgotten Swab

AT a recent inquest at Oxford on the death of an elderly woman after an emergency operation, evidence from necropsy indicated that a swab was found in the pelvis. Death was stated to be due to cardiac failure and pulmonary congestion associated with partial intestinal obstruction following an operation for the relief of an intestinal volvulus.

The surgeon who had operated produced specimen swabs, large and small. It was a large swab which had been found in the body. Asked by the coroner whether it was not a big object to be overlooked, the witness agreed that it appeared large when spread out, but thought that in this case it must have been crumpled up into a small space and hidden behind a layer of intestine. The coroner directed his questions to ascertain the practice of counting swabs and the responsibility for the count. The surgeon said he usually tried to know how many were in use but the final count provided a check. The practice was for the nurses to record on a slate the numbers and types used; he himself invariably inquired about the count, if he had not already had the information. No similar accident had happened to him before, but his more senior colleagues could recall at least one example in the course of their professional careers.

There was evidence that a nurse had gone off duty and been replaced by another nurse during the course of the operation; she went to supper at 8 P.M. and returned to duty half an hour later. One witness observed that a change-over of this kind was unusual and undesirable; there was, however, no hospital regulation to prohibit it.

The coroner returned a verdict of death by misadventure. It seemed reasonable, he said, that a surgeon should keep a rough idea of the number of swabs used, but he could not be expected to have an exact memory of it; it was not surprising that he failed to remember this particular swab. A mistake had been made somewhere; possibly the additional swabs called for were not entered on the slate or one was missed in the final count. As regards the change-over of nurses, he did not suggest new regulations on this subject; but, if the replacement of a nurse during an operation became necessary, there ought to be a very clear understanding between the relieving nurse and the relieved nurse.

are greatly improved if penicillin and sulfasuxidine are added. Anti-amœbic drugs appear to possess synergistic properties which are a justification of the old blunderbuss treatment.

2. Although imperfect, carbarsone is moderately potent and will produce immediate cure in 48%. Its shortcomings are better judged by the high absolute-failure rate of 42%, which is much higher than that of emetine.

3. Emetine bismuth iodide appears to have a higher success-rate than emetine, but the more objective absolute-failure rate is nearly the same. In series U the patients were treated with powdered emetine bismuth iodide tablets placed in gelatin capsules. In a previous series the unbroken tablets were used with most disappointing results; whole tablets were removed from the bowel at sigmoidoscopy and many more were shown intact radiologically. The clinical results were much worse than in series U and 5 patients died before we appreciated the reason. It is beyond belief that manufacturers continue to supply emetine bismuth iodide pills and that gelatin-coated powders are unobtainable.

4. Dr. Todd states that sulphonamides and penicillin are best reserved for cases whose attacks do not take a favourable course. Many cases of amœbic dysentery are so severe from the onset that both these drugs are of immense value. After all, when given separately and alone they are capable of curing the disease and statistically differ but little from emetine.

5. We have now treated 23 cases with 'Aureomycin.' It is the most potent curative agent which we have yet handled.

6. We have found with serial sigmoidoscopies that a proportion of cases which still have open ulcers at 20 days proceed to complete healing at 27 days or later without *further treatment. With the drugs at present in common* use we have found that many ulcers take 3–4 weeks to heal.

7. We believe that amœbic dysentery is a serious illness requiring precise diagnosis and coordinated treatment. In view of the time required for healing, forward units are at present unsuitable places for treatment.

8. The sulphonamides alone are capable of rendering patients free of amœbæ.

The normal treatment of bacillary dysentery is with these drugs. If all cases of dysentery, both bacillary and amœbic, were treated in forward units without microscopy, all would be treated with sulphonamides. The result would be a disastrous suppression of the diagnosis of amœbiasis and a consequent rise in the number of chronic undiagnosed cases.

URTICARIA COMPLICATING STREPTOMYCIN THERAPY

SIR,—I was interested to read Captain Lindars's article in your issue of Jan. 21. The following case is somewhat similar to that described by him.

A girl, aged 15 years, with tuberculous meningitis, was started on streptomycin treatment on July 16, 1949. She received forty intrathecal injections of 100 mg. each; and she also had 2 g. intramuscularly each day until Oct. 21, when the dose was reduced to 1 g. daily owing to increasing deafness. This dose was maintained until Jan. 11, when she received her 180th intramuscular dose. The streptomycin was then stopped. She had also been on 'Promizole'—1 g. daily—from Dec. 1. This was continued after the streptomycin was stopped.

On Jan. 16, five days after streptomycin was stopped, she developed a profuse urticarial rash on her body and limbs; and she also complained of diplopia. She had ptosis on the left side and her left pupil was dilated. She vomited once that day.

All drugs were stopped. The rash cleared gradually in three days. The diplopia is still persisting slightly (8 days after the appearance of the rash). Her ptosis is much improved. However she has vomited once daily since the rash appeared. She was afebrile after her intrathecal course was completed on Sept. 21 until Jan. 21. On the 4 days since then her evening temperature has varied between 100° and 101°F.

THE CAPENER NAIL-PLATE

SIR,—It is true, as stated last week by Mr. C and Mr. Hosford, that many devices (in both o two pieces) have been invented for the fixation of chanteric fractures. The method is a well proved and not only saves life but also makes easier the of such cases and minimises the duration of care. Even if Coltart and Hosford are unable to that the method is "invaluable," no doubt allow that, at any rate, it is *valuable* if it achieves results stated.

The nail-plate to which my name has been is, I think, an improved version of the Neufeld dev If eponymous names are to be used, the two should joined. Surely, however, it is time that eponyms discarded. It is given to few to be original. The catalogues of surgical instrument makers are cluttered with illustrations of appliances many of which prove poor memorials to the craftsmen named.

Medicine and the Law

A Forgotten Swab

AT a recent inquest at Oxford on the death of an elderly woman after an emergency operation, evidence from necropsy indicated that a swab was found in the pelvis. Death was stated to be due to cardiac failure and pulmonary congestion associated with partial intestinal obstruction following an operation for the relief of intestinal volvulus.

The surgeon who had operated produced specimen swabs, large and small. It was a large swab which had been found in the body. Asked by the coroner whether it was not a big object to be overlooked, the witness agreed that it appeared large when spread out, but thought that in this case it must have been crumpled up into a small space and hidden behind a layer of intestine. The coroner directed his questions to ascertain the practice of counting swabs and the responsibility for the count. The surgeon said he usually tried to know how many were in use but the final count provided a check. The practice was for the nurses to record on a slate the numbers and types used; he himself invariably inquired about the count, if he had not already had the information. No similar accident had happened to him before, but his more senior colleagues could recall at least one example in the course of their professional careers.

There was evidence that a nurse had gone off duty and been replaced by another nurse during the course of the operation; she went to supper at 8 P.M. and returned to duty half an hour later. One witness observed that a change-over of this kind was unusual and undesirable; there was, however, no hospital regulation to prohibit it.

The coroner returned a verdict of death by misadventure. It seemed reasonable, he said, that a surgeon should keep a rough idea of the number of swabs used, but he could not be expected to have an exact memory of it; it was not surprising that he failed to remember this particular swab. A mistake had been made somewhere; possibly the additional swabs called for were not entered on the slate or one was missed in the final count. As regards the change-over of nurses, he did not suggest new regulations on this subject; but, if the replacement of a nurse during an operation became necessary, there ought to be a very clear understanding between the relieving nurse and the relieved nurse.

Obituary

HENRY GORDON CAMPBELL

L.R.C.P.E., L.D.S.

H. Gordon Campbell, who died at his home in e, on Jan. 17, at the age of 79, was the first occu- f the first chair of dental surgery in Scotland. pointment was apt to the tradition of his family, father, Mr. Walter Campbell practised as a dentist ndee, and his brother, the late Dr. W. Graham ell, was dean of the Dental Hospital in Dundee s start in 1919. On his retirement in 1938 Gordon ell succeeded him in that office.

n Dundee High School he went to Edinburgh sity, but when he was 19 he broke off his studies to go on the stage in London under the name of n Doune. He also did some journalism, and he friend of Richard Le Gallienne. But this break rofessional work was after all only an interlude, e returned to Edinburgh to finish his studies. 4 he qualified in medicine and dentistry and settled ctice in Dundee. In 1913 he was appointed dental to the Dundee school board and for some years as also dental surgeon to the maternity and welfare clinic.

e founder of the Dundee Dental Health Association, s also a former president of the Odonto-Chirurgical ty of Scotland and of the Dundee Dental Club. he dental school he lectured in dental anatomy physiology, and he was lecturer in oral hygiene in ourse for the diploma in public dentistry conducted t. Andrews University. He was appointed to the r of dental surgery there when it was founded in . He retired in 1946.

e leaves a widow and two sons. The elder, Mr. W. don Campbell, is surgeon to the Royal Dundee rmary, but like his father and his grandfather he holds a dental qualification.

Appointments

RRETT, G. M., B.A., M.D. Camb., M.R.C.P.: consultant physician, Lancaster and Kendal group of hospitals.

RRY, D. Mc R., M.B. Dubl., D.M.R.D.: radiologist, Bolton and district group of hospitals.

HR, GERHARD, M.R.C.P.: pathologist, Burnley and district group of hospitals.

NHAM, G. H. H., M.B. Manc., M.R.C.P.: physician, Ashton, Hyde, and Glossop group of hospitals.

TCLIFFE, E. W., M.B.E., M.S. Lond., F.R.C.S.: consultant orthopædic surgeon, Tunbridge Wells and Hastings group of hospitals.

YLE, E. P., M.B. Edin., D.P.M.: deputy superintendent (psychiatrist), Shelton Hospital, Shrewsbury.

OWN, D. J. A., M.B. Lond., D.A.: anæsthetist, Rochdale and district group of hospitals.

RTON-BROWN, JEAN, M.D. Lond., F.R.C.S., M.R.C.O.G.: consultant obstetrician and gynæcologist, Canterbury and Isle of Thanet.

RSON, JAMES, M.D. Belf., M.R.C.P., D.P.H., D.C.H.: physician, South Cheshire group of hospitals.

THBERT, JAMES, M.D. Glasg., F.R.F.P.S., D.P.H.: consultant chest physician, Leicester chest service.

AMANSKI, MARK, M.D. Lwow: senior resident M.O., Southport Promenade Hospital.

ANIELS, H. A., M.B. Dubl., F.R.C.S., F.R.C.S.I.: consultant surgeon, Barrow and Furness group of hospitals.

ARBISHIRE, S. B., B.A., M.B. Camb.: part-time consultant anæsthetist, Barrow and Furness group of hospitals.

ICK, T. B. S., M.D. Manc., M.R.C.P.: physician, Wigan and Leigh group of hospitals.

RAKE, E. P. H., M.B. Camb., F.R.C.S.: consultant surgeon, Lancaster and Kendal group of hospitals.

ITZGERALD, T. B., D.S.C., M.B. Birm., F.R.C.S.E., M.R.C.O.G.: gynæcologist, Ashton, Hyde, and Glossop group of hospitals.

IFFORD, L. A., M.B. Manc., D.A.: anæsthetist, Ashton, Hyde, and Glossop group of hospitals.

RAY, A. J., M.B. Camb., D.A.: part-time consultant anæsthetist, Preston and Chorley group of hospitals.

RIFFITH, J. L., M.B. Camb., F.R.C.S.: consultant thoracic surgeon, Devon and Cornwall area.

RIFFITHS, ARTHUR, M.R.C.S., D.M.R.D.: radiologist, Macclesfield and Crewe group of hospitals.

AY, W. J., M.B. Camb., M.R.C.P.: consultant physician, Lancaster and Kendal group of hospitals.

ORROCKS, J. E., M.B. Manc.: consultant pathologist, Barrow and Furness group of hospitals.

ONES, M. T. I., M.D. Lond., D.P.H.: deputy M.O.H. and deputy school M.O., Bournemouth.

IDD, J. D., M.B. Camb., M.R.C.P.: physician, Aylesbury and High Wycombe group of hospitals.

OWE, J. J. H., M.D. Durh., M.R.C.P., D.P.M.: psychiatrist, St. Crispin Hospital, Northampton.

ACFADYEN, W. A. L., M.D. Edin., M.R.C.P.: consultant physician, Blackburn and district group of hospitals.

PAINE, D. H. D., M.B. Lond., D.P.M.: deputy superintendent (psychiatrist), St. Margaret's Mental Defective Colony, Great Barr, Birmingham.

RACKOW, F. I., M.B. Lond., M.R.C.P.: senior medical registrar, St. Andrew's Hospital, London.

REWELL, R. E., M.D. Lond., M.R.C.P.: consultant pathologist, United Liverpool Hospitals.

RICHMOND, D. A., M.B. Manc., F.R.C.S.: orthopædic surgeon, Burnley and district group of hospitals.

ROYDE, C. A., M.D. Lond., D.P.H.: asst. administrative M.O., headquarters staff, Sheffield regional hospital board.

SHAW, D. A. F., M.B. Manc., M.R.C.O.G.: gynæcologist, Stockport and Buxton group of hospitals.

SOMMERVILLE, JAMES, M.B. Glasg.: dermatologist i.c. wards at Western Infirmary, Glasgow.

SPACEK, M. R. W., M.B. Dubl., D.A.: part-time consultant anæsthetist, Lancaster and Kendal group of hospitals.

STOKES, W. J., M.D. Lond., M.R.C.P., D.OBST. R.C.O.G.: physician, Aylesbury and High Wycombe group of hospitals.

STRAHAN, A. W. B., M.B. Edin., F.R.C.S.: consultant surgeon, Barrow and Furness group of hospitals.

TAYLOR, W. V., M.B. Lond., D.M.R.: radiologist, Oldham and district group of hospitals.

WAIND, A. P. B., D.S.C., M.D. Leeds, M.R.C.P.: consultant physician, Barrow and Furness group of hospitals.

WATT, LESLIE, M.D. Aberd.: venereologist, Rochdale, Ashton, and Oldham venereal-disease clinics.

Notes and News

ADMINISTRATION OF THE HEALTH SERVICES

In its report last year on the National Health Services, the Select Committee on Estimates[1] suggested that, while the costs of executive councils seemed to be reasonable, a review might be necessary later when the health services had settled down. Replying to this and to other suggestions by the committee, the Ministry of Health and the Department of Health for Scotland say[2] that the administrative machinery of these councils is being examined by organisation and methods officers; but "generally it seems that the administration of these bodies is economical." As to the committee's recommendation that entry into general practice should be facilitated, the Medical Practices Committee for England and Wales has completed its survey of the country; and its report, naming the areas where further practitioners are mostly urgently needed, should encourage doctors to settle in those places where the prospect of successfully establishing themselves is great. Furthermore, executive councils have been asked to consider the steps needed to increase the number of practitioners in areas classed by the Medical Practices Committee as urgently needing more doctors.

> "It has been suggested to Executive Councils that these steps might include advertising the need for a specified number of doctors to set up practices in the area, it being made clear that a fixed annual payment of £300 would normally be made in such cases; and that in sparsely populated or otherwise particularly unattractive areas the possibility should also be considered of recommending to the Minister that a payment from the Inducement Fund should be made."

With regard to the Select Committee's suggestion for reducing the number of cases where prior approval of treatment has to be obtained from a dental estimates board, "the Department's dental advisers are unable to recommend that there should be any reduction . . . nor has any recommendation for such a reduction been received from the Dental Estimates Boards."

In the field of hospital administration, the Central Health Services Council has set up a committee to inquire into this; and in Scotland there is a Standing Advisory Committee on hospital and specialist services. A joint committee of the Central Health Services Council and of the Scottish Health Services Council has been considering which "borderline" products are not properly to be regarded as drugs; and a further joint committee is considering what drugs ought (or ought not) to be prescribed.

The Minister of Health rejects, as wasteful, the committee's proposal for an internal efficiency audit by officers of regional hospital boards. He agrees, however, "that a uniform system of costing should be devised as soon as practicable for the Hospital Services in England and Wales, the only questions being the precise system to be adopted and the timing of its introduction. . . . As an interim measure hospitals have been asked to supplement the annual financial returns with statistical data which will enable costs per day or week to be calculated for each head of expenditure, thus providing a somewhat elementary form of costing." In Scotland the only costing units employed are beds and patients, but a more sensitive system of functional costing is being developed.

INFECTION AND THE COMMUNION CUP

The use of a common cup at the communion table has potential dangers which have been recognised probably from early times, and certainly from the time of Edward VI, when an injunction in the first prayer-book requires the priest to administer "last of all to the sick person." The danger comes, however, not from the person who is evidently sick, but from the unwitting carrier of harmful organisms, whether of mild disorders like the common cold, or more serious conditions such as tuberculosis. The danger is probably slight on the whole, but the notion of it is disquieting, and it may gain in importance in times of epidemic. With these considerations in mind the Rev. T. Grigg-Smith, canon chancellor of Portsmouth Cathedral, has written a short clear book[3] on intinction, the method of dipping the wafer in the wine and placing it directly on the communicant's tongue. He explains that the use of this inoffensive need do no violence to the traditional symbolism of eucharist; and quotes the resolution of the Lambeth ference, 1948, that "any part of the Anglican C by provincial regulation according to its own c procedure has liberty to sanction administration by i as an optional alternative to the traditional method. There are undoubtedly good hygienic grounds for the method universal.

"TOMORROW'S A WONDERFUL DAY"

Jewish children from the concentration camps of Europe are still entering Palestine in their th They are nearly all orphans with much misery to much bitterness to unlearn. Fifteen years ago, when an generation of such children were flying from Nazi the Youth Aliyah movement began the work of rescuing caring for them—not merely for their bodies but for hampered minds and spirits. By 1939 some 5000 had received; by the end of last year the total had 45,000; and another 15,000 are expected in 1950. They are received in 220 settlements and institutions, and are taught agriculture and crafts as well as being given ordinary schooling. The life in one such settlement was shown in a film which received great praise at the Edinburgh Festival last year. It was shown again in London, on Jan. 26, to an Jewish doctors and others.

Tomorrow's A Wonderful Day reveals the settlement as it appeared to one sullen suspicious boy, from the time he to the time when he could bring himself to laugh and and work again. All the actors are the children themselves. The photography is perfect, and leaves in the mind's some unforgettable pictures—the boy stealing bread to away; the thin musician's face of the child conducting orchestra; garlanded small children carrying the first- girls dancing lightly in bare feet; the struggle to b fence of great stones (not wire); the boy running with torch which commemorates the Maccabees; a child l the seven candles in their branched stick. All th the training of these children run the faith and custo Israel. It is as though they are constantly, wordlessly, "You have no father, but you now have a country, and you come of a race with a great religious and histo tradition. You are no longer alone, you are one of a fam and you will be cherished as the sons and daughters of you own people." This is the sort of security such children need a sense of belonging to something strong, safe, and friendly; and they have the added joy of being able to share in building up their country and making its barren places fertile.

Gentiles will be as much moved by the film as Jews, though perhaps they may regret the evidence of that intense inward-turning which has so often, and so disastrously, cut the Jewish people off from the rest of the world. The children are taught to read and write in Hebrew, and their songs deal often with the destruction of enemies (though who can blame them for that?). English audiences may also regret the commentary, delivered in an American voice, which crosses the t or dots the i far too often. Nevertheless, this a beautiful and remarkable film, which will surely stir many to contribute to the work of Youth Aliyah.

University of Oxford

On Jan. 19 the degree of B.M. was conferred on R. O. E Heape and M. J. P. Johnston.

University of Cambridge

To commemorate the Pavlov centenary Prof. J. Z. You F.R.S., will give a lecture on Wednesday, Feb. 8, in the phys logical laboratory. He is to speak on the Nature of the Learning Process.

University of London

On Feb. 15 and 17 Dr. Z. M. Bacq, professor of therap pathology in the University of Liége, will lecture at St. Mary's Hospital Medical School, London, W.2, at 5 P.M. At the first lecture he will speak on the Metabolism of Adrenaline, and at the second on the Substances which Increase the Sensitivity of Tissues to Potassium Ions.

Medical Photography

An exhibition of medical photography will be held at the photographic department, St. Mary's Hospital Medical School, from Feb. 7 to 13 (open from 2 P.M. to 6 P.M. Saturday, 10 A.M. to 1 P.M.).

.P.M.—F. O'D. Finigan.

.P.H.—J. C. Day, Roy Franey, W. C. Kingston, D. D. Maitland, McG. Rogan, Asa Singh, W. M. Stewart, Peter Westcombe.

tional Institute for Medical Research

The institute has moved from Hampstead to Mill Hill d the address is : National Institute for Medical Research, e Ridgeway, Mill Hill, London, N.W.7 (Tel. : Mill Hill 66). The building at Hampstead has been retained by the dical Research Council to house one division of the institute d the whole or parts of several research units. The address ll be : Medical Research Council Laboratories, Holly Hill, mpstead, London, N.W.3 (Tel. : Hampstead 2232).

International Anatomical Congress

This congress is to be held at Oxford from July 25 to 28 under the presidency of Prof. W. E. Le Gros Clark, F.R.S. Further information may be had from the congress secretary, Dr. Graham Weddell, Department of Human Anatomy, University Museum, Oxford.

W.H.O. European Regional Conference

The European health conference which, as we announced last week (p. 189), is to be held with a view to establishing a regional organisation for Europe, has been postponed from March 6. It will now be held during or after the third World Health Assembly, which opens in Geneva on May 8.

National Hospital, Queen Square

Dr. Helgi Tómason, of Iceland, will give a lecture at this hospital on Friday, Feb. 10, at 5 P.M., on the Occurrence of Neuropsychiatric Disorder in Twins. At the same hour on Monday, the 13th, he will speak on the Reactions of the Human Nervous System to Weather and Climate in Northern Cold and Temperate Zones.

Medical Mycology Lecture-demonstrations

The Institute of Dermatology is holding a series of lecture-demonstrations (including practical work) on medical mycology at the London School of Hygiene and Tropical Medicine during March on Mondays and Fridays at 2 P.M. Full details can be had from the secretary of the institute, 5, Lisle Street, London, W.C.2.

Congress on Hæmatology

The congress of the International Society of Hæmatology will be held in Cambridge from Aug. 21 to 26 under the presidency of Sir Lionel Whitby. There will be discussions on anæmias, leukæmias, blood coagulation, and immunohæmatology. Applications should be sent as soon as possible to the congress secretary-treasurer: Dr. Martin Hynes, Department of Medicine, University of Cambridge.

Mental Health and the Family

The National Association for Mental Health is holding a conference on this subject at the Seymour Hall, Seymour Place, London, W.1, on March 23 and 24. The speakers will include Dr. J. L. Halliday. Further particulars may be had from the conference secretary of the association, 39, Queen Anne Street, London, W.1.

Association of Psychiatrists of the Scottish Western Region

On Nov. 18, at a meeting to which all psychiatrists known to be working in the Western Region were invited, this association was formed with the following office-bearers: chairman, Prof. T. Ferguson Rodger; vice-chairman, Dr. A. Dick; hon. secretary, Dr. Hunter Gillies, Crichton Royal, Dumfries; treasurer, Dr. M. M. Whittet.

Festival of Britain 1951

The theme of the festival exhibition, which is to be held in London on the South bank of the Thames in 1951, is that British contributions to civilisation have resulted from a combination of two forces—the initiative of the People and the resources of their Land. Besides the section on health in the sequence on the People, other advances in medical fields, such as industrial medicine and welfare, will be shown in the sections on power and production. Under the Dome of Discovery, which links the two great sequences, there will be exhibits, in the section on exploration, on advances in tropical medicine.

Conference on the Application of Scientific Methods

The Medical Research Council will hold a conference on this subject for industrial and Service medical officers at the London School of Hygiene, Keppel Street, W.C.1, from March 29 to 31. Lecture-demonstrations will be given by the staff of the council and by associated scientific workers. Prof. A. Bradford Hill, D.SC., Prof. J. R. Squire, and Dr. Alice Stewart will speak on Scientific Method in Field Surveys; Sir Frederic Bartlett, F.R.S., Prof. W. E. Le Gros Clark, F.R.S., and Mr. T. Bedford, D.SC., on the Improvement of Human Performance by Laboratory Studies; and Dr. Donald Hunter, Dr. J. M. Barnes, and Dr. C. M. Fletcher on the Investigation of Health Hazards. Applications for enrolment should be sent to the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, as soon as possible.

Medical Artists' Association of Great Britain

This association is holding an exhibition at 1, Wimpole Street, London, W.1, from Monday, March 27, to Saturday, April 1.

Military Medicine

The 13th meeting of the Office International de Documentation de Médecine Militaire will be held in Monaco from May 3 to 7. Further information may be had from the secretariat, 2a, Boulevard des Moulins, Monte Carlo.

British Health Resorts Association

At a meeting held on Jan. 18 it was unanimously decided to revive this association, and a further meeting is being held today Friday, Feb. 3, at 4 P.M., at 11, Chandos Street, London, W.1, to elect officers. Dr. M. B. Ray, is the acting hon. secretary, and the temporary address of the association is Bourdon Street, Berkeley Square, W.1 (Mayfair 7330).

St. Thomas's Hospital Musical Society

This society will perform Mozart's *Requiem* on Tuesday, Feb. 14, at 8.15 P.M. (ending about 9.30 P.M.) in St. Mary's Church, Bryanston Square, London, W.1. Dr. W. Dykes Bower will conduct, and the organist will be Mr. J. Dykes Bower, organist at St. Paul's Cathedral. No tickets are required.

Medical Films

The Royal Society of Medicine and the Scientific Film Association will hold a joint meeting on Feb. 21, at 5.30 P.M., at 1, Wimpole Street, London, W.1, when Sir Kenneth Goadby will preside and Prof. R. J. S. MacDowall, Mr. C. J. Longland, and Dr. R. G. W. Ollerenshaw will open a discussion on What Constitutes the Ideal Medical Film.

Course on Industrial Medicine

The Nuffield department of occupational health of the University of Manchester is holding a course for industrial medical officers and nursing sisters from March 27 to April 1 on the Rôle of Industrial Medicine in the Welfare State. Further particulars will be found in our advertisement columns.

Medical Film Makers

A film-show discussion for makers of medical films will be held by the medical committee of the Scientific Films Association at Guy's Hospital on the third Wednesday of February, March, April, and May, from 6 P.M. to 8 P.M. Tickets may be had from the association, 4, Great Russell Street, London, W.C.1.

Dental Mission to New Zealand

An official mission is leaving at the beginning of February to obtain a report on the New Zealand system of school dental nurses. The members of the mission are: Prof. R. V. Bradlaw, M.D.S., F.R.C.S., dean of the dental school and professor of dental surgery at Durham University; Dr. T. H. J. Douglas, F.D.S. R.C.S., senior dental officer of the Department of Health for Scotland; Mr. H. T. Roper-Hall, M.B., F.D.S. R.C.S., president-elect of the British Dental Association; Mr. W. G. Senior, PH.D., F.D.S. R.C.S., principal dental officer, Ministry of Health; and Dr. A. T. Wynne, F.D.S. R.C.S., medical officer, Ministry of Education.

Mr. Ewing on European Health Services

After his six weeks' study of health, education, and social-welfare schemes in four European countries Mr. Oscar Ewing, the U.S. Federal Security Administrator, said that he had come home with even greater confidence in President Truman's proposal for national health insurance in the United States. According to *B.U.P.*, he believes that "the British plan is totally unsuited for the United States. In England, the health service is part of a broad programme to reorganise the basic social and economic structure of the country and eight-ninths of the cost comes out of general tax revenues. This is utterly foreign to the President's proposal." The latter is "strictly an insurance plan on a pay-as-you-go basis and intended solely to eliminate the dollar barrier between the average American and the medical care he needs." Mr. Ewing feels that the Swedish scheme, under which each patient pays one-third of the doctor's fees each time he needs medical attention, should be given some thought. It is intended to cut down abuses of the system by both doctor and patient.

British Medical Students Association

The London Hospital branch of the association
on Tuesday, Feb. 21, at 5.30 P.M., when Sir Hugh
will speak on the Injured Workman, and on Tuesday,
when Dr. Alice Stewart will speak on Social Medicine.
meetings will be held at the hospital at 5.30 P.M.

Sir Henry Dale, O.M., has left for a three months'
tour in New Zealand and Canada for the British Council.

The Hunterian Society has issued its *Transactio*
1948–49 session. The hon. secretaries of this soc
Mr. C. A. Francis and Dr. Franklin Bicknell.

Diary of the Week

FEB. 5 TO 11

Tuesday, 7th

UNIVERSITY OF LONDON
5 P.M. (Westminster Medical School, Horseferry Road, S.W.1
Prof. J. G. G. Borst (Amsterdam): The Circul
Disease.
5.15 P.M. (University College, W.C.1.) Dr. L. C. Th
Visual Physiology. (First of three weekly lectures)

Wednesday, 8th

ROYAL FACULTY OF PHYSICIANS AND SURGEONS, 242, St. Vin
Street, Glasgow
5 P.M. Dr. G. J. Aitken: Diagnosis of Congenital Heart
(James Watson lecture.)

Thursday, 9th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. Denis Browne: Congenital Deformities o
Urethra, Vagina, and Anus. (Hunterian lecture.)
INSTITUTE OF DERMATOLOGY
5 P.M. Dr. A. D. Porter: Urticaria.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, S.W.1
4.30 P.M. Dr. Desmond Curran: Psychiatry
demonstration.
ADLERIAN SOCIETY OF GREAT BRITAIN
8 P.M *Medical Section.* (11, Chandos Street, W.1.)
F. L. Golla: Psychotherapy and Responsibility.

Friday, 10th

NATIONAL HOSPITAL, Queen Square, W.C.1
5 P.M. Dr. Helgi Tomasson (Iceland): Occurrence of
psychiatric Disorder in Twins.
MAIDA VALE HOSPITAL MEDICAL SCHOOL, W.9
5 P.M. Dr. Helen Dimsdale: Neurological demonstration.
WEST-KENT MEDICO-CHIRURGICAL SOCIETY
8.30 P.M. (Miller Hospital, S.E.10.) Mr. Alistair Gunn: The
Discomforts of Pregnancy.

Births, Marriages, and Deaths

BIRTHS

BUCHANAN.—On June 21, in Edinburgh, the wife of Dr. J. W
Buchanan—a daughter.
BYRNE.—On Dec. 15, in Derby, the wife of Dr. P. H. Byrne—a son.
GOODMAN.—On Jan. 10, in London, to Dr. Ruth Goodman (
Sabel), wife of Mr. C. J. Goodman—a daughter.
JOHNSTON.—On Jan. 23, the wife of Dr. J. S. Johnston—a son.
KENDALL.—On Jan. 22, in London, the wife of Dr. John Ken
—a daughter.
LYDON.—On Jan. 17, in London, the wife of Dr. F. L. Lydon
a daughter.
MCALLEN.—On Jan. 22, the wife of Dr. P. M. McAllen—a daught
ROSS.—On Jan. 26, in Edinburgh, the wife of Mr. J. A. R
M.B.E., F.R.C.S.E.—a daughter.
SCHILLER.—On Jan. 29, at Didsbury, the wife of Dr. George Sc
—a daughter.
WHITE.—On Jan. 26, at Southborough, the wife of Dr.
White—a son.

DEATHS

ARNISON.—On Jan. 27, at Newcastle upon Tyne, William Drew
Arnison, M.A., M.D. Durh., F.F.A.R.C.S., aged 85.
COWPER.—On Jan. 28, in Cape Town, South Africa, Claude Mar
Lovell Cowper, M.R.C.S., aged 70.
DOUGLAS.—On Jan. 26, in London, Archibald Robert John Do
M.D. Lond., F.R.C.S., D.P.H.
MONTGOMERY.—On Jan. 26, in Kalk Bay, South Africa, Step
King Montgomery, B.A., B.SC. W. Australia, M.D. Lond.,
SMITH.—On Jan. 26, at Worthing, Henry Sandford Smith, M.R
STEWART.—On Jan. 22, in Manchester, Charles Hugh Stew

THE WELLCOME RESEARCH LABORATORIES, BECKENHAM

s pharmacological and clinical experience with ninosalicylic acid (P.A.S.) (Lehmann 1946a) accumu- s, it seems possible to discriminate between its direct eriostatic effect on the parasite and its various rmacological effects on the host.

he bacteriostatic action of P.A.S. against tubercle illi in man, described by Lehmann (1946a and b, 7a and b), has been amply confirmed by Sievers 46) and others, and extended to studies on laboratory mals by Youmans (1946), Feldman et al. (1947), umans et al. (1947), Alin and Difs (1947), Bray et al. 48), and Duca et al. (1948). Further, a direct effect on ercle bacilli identified in body-fluids after P.A.S. has n given to man has been commented on by most ical observers. Dempsey and Logg (1947) noted the ered morphology of the bacilli and described beaded, iated, and granular forms; they believe that the acid- t granules may survive after the acid-fast cell has appeared. Similar observations were made by Erdei l Snell (1948), Steinlin and Wilhelmi (1948), and gley and Logg (1949), the last workers speaking of attered bacilli."

The antipyretic effect of P.A.S. is noted by all observers. is to be seen in the published hospital charts of the t two patients treated by Vallentin (Lehmann 1946a). dei and Snell (1948) suggest that a direct pharmaco- ical mechanism is involved. Whether the rapidly veloping euphoria observed by all clinical workers in erculous patients treated with P.A.S. is a direct effect follows the alleviation of symptoms has not been wn by previous reports.

There is no unanimity about side-effects, a fact noted Erdei and Snell (1948), but nausea and sickness usually observed; some cases develop sensitisation osyncrasy (Hemming and Stewart 1949), and crystal- ia or aciduria, with occasional hæmaturia, has been en (Nagley and Logg 1949); but no serious toxic ects have been reported.

We report here the results of a study of the pharmaco- gical and antibacterial effects of P.A.S. in animals d man.

Clinically, the first observed effect is a peripheral sodilatation seen within about half an hour of giving e initial dose. The areas habitually exposed to sunlight e most affected.

Of more gradual onset is an antipyretic effect which ay be seen within 48–72 hours. This is greatest in atients with raised swinging temperatures and is less efinite or absent in those with only slight pyrexia. he fall in temperature occurs without any perceptible weating, which raises the question whether the increased eat loss by radiation due to the observed peripheral asodilatation is sufficient to explain the antipyretic ffect.

Also observed within 48–72 hours is the subjective mprovement in the patient, generally referred to as a eeling of well-being. If this is concurrent with a well- narked antipyretic effect, it is tempting to look no urther for an explanation. But the sense of well-being is also seen in apyrexial patients and in those with progressive disease which becomes terminal. In the absence of a more precise description it is convenient to call it a detoxicating effect. Whether this detoxicating effect is due to a direct reaction between P.A.S. and the parasite's metabolic products was one subject of our inquiry.

The direct antibacterial effect on the tubercle bacillus which is seen on microscopical examination did not appear until about the seventeenth day of therapy in our series.

METHODS AND CLINICAL MATERIAL

Sodium *p*-aminosalicylate 30 g. daily was given in six doses distributed over the waking hours, the schedule being similar to that described by Nagley and Logg (1949). A flavoured elixir containing 3 g. of P.A.S. in each ounce is the most convenient preparation. Potassium citrate 1 g. twice daily was given, if required, to keep the urine alkaline. A single dose of P.A.S.—e.g., 7·5 g.—is quickly absorbed, produces a peak in the blood-level within $^1/_2$–1 hour, and is rapidly excreted in about 4 hours. The curves (fig. 1) illustrate typical estimations. It follows that isolated estimations of the blood-P.A.S. level are of little value, but if they are to be relied on they should be made 30 minutes after a dose.

Estimation

Since P.A.S. is firmly bound to plasma and tissue protein, the problem is to free, in an unaltered state, the total quantity present. This is achieved by adequate dilution, and disaggregation at an acid pH. The resulting dilute solution may be diazotised and coupled by the Bratton and Marshall method, but the colours are poor; a more suitable yellow colour is obtained by allowing the free arylamino group of P.A.S. to react with *p*-dimethyl-aminobenzaldehyde. The pH of the reaction is critical and should lie between 2·0 and 2·2 for the maximum colour development. The method is described by Short (1949) and gives recoveries of 95% or better.

Choice of Cases

The P.A.S. was given to 64 patients with pulmonary tuberculosis; 53 of them received the drug alone,

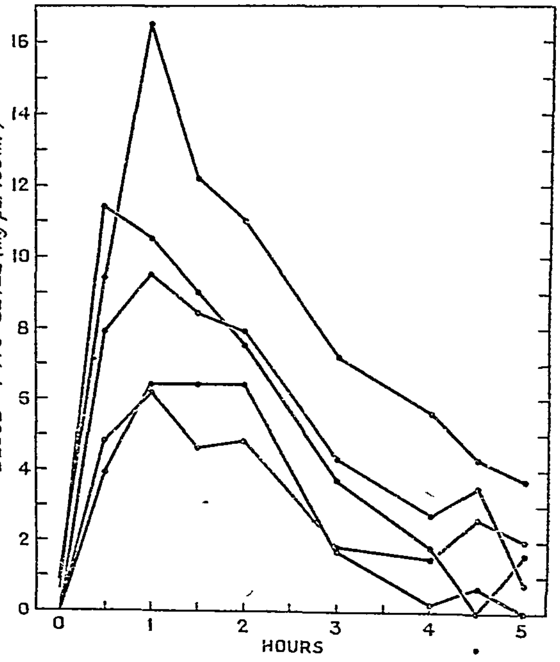

Fig. 1—Blood-P.A.S. levels in 5 patients given a single dose of P.A.S. 7·5 g., showing that by the third hour 2 patients had blood-P.A.S. of less than 2 mg. per 100 ml.

whereas 11 also received other chemotherapeutic agents. Patients were selected with a specific target in view. Thus 7 patients, recently discharged from sanatoria as having received maximum benefit (generally a euphemism for a bad prognosis), were given chemotherapy with the object of making them fit for major surgery ; 5 of these have since been accepted for operation and 2 rejected. In 17 patients treated by artificial pneumothorax for 6 months without complication, P.A.S. therapy was given at the same time ; this group included examples of those "hot" lesions in which immediate active intervention would normally entail an unjustifiable hazard of tuberculous empyema ; others were examples of bad risks with peripheral tension cavities. P.A.S. was given to 8 patients with complicated pleural effusions from which tubercle bacilli were isolated ; 2 of these had frank tuberculous empyemas, 1 of which was secondarily infected. A further 12 patients were admitted for surgical intervention after chemotherapy, and 10 of these have been accepted. There were 13 examples of bilateral tuberculosis with limited contralateral disease, exudative in 10, fibrocaseous in 3, and 2 patients presented with apical infiltration, complicated by a massive homolateral pleural effusion. Combined treatment with P.A.S., 'Sulphetrone,' and streptomycin was given to 2 patients with bronchopneumonia and 1 with tuberculous meningitis associated with pulmonary tuberculosis. The remaining 2 patients were in an advanced stage of tuberculosis, and for them no specific target was sighted.

RESULTS

Table I summarises the results obtained in these 64 cases. For convenience the grouping is based on a descriptive rather than a pathological classification. The therapeutic assessment of P.A.S. is based on the patient's general condition, changes in the erythrocyte-sedimentation rate (E.S.R.), the temperature, the pulse, and the bacteriology of body-fluids, clinical and radiological findings, and—in particular—on the achievement of the specific target.

We have not attempted a final assessment of the chemotherapeutic value of P.A.S. but have tried to emphasise the apparent clinical discrepancies which directed our attention to effects peculiar to this drug.

The changes seen in the tuberculous patient given P.A.S. may be divided into three groups. Group I comprises the effects of the drug on fever, E.S.R., blood-counts, and hæmoglobin level ; these are associated with and probably caused by the pharmacological dilator action of P.A.S. on the peripheral blood-vessels. The effects in group II are the direct ones on the tubercle bacillus, which suffers changes for a variable period, beginning about fourteen days after the first exhibition of P.A.S. ; with these are associated the changes which may be seen on X-ray films. Group III consists of toxic effects.

I. Effects on Fever, E.S.R., and Blood

The effect of P.A.S. on fever varies with its extent. When the temperature is high and swinging there is a rapid lysis to a range of about 99·5–100·5°F, usually within 48–72 hours. If the temperature excursion is already only about 99·5–100·5°F the alteration is less noticeable or absent. Usually, but not invariably, night-sweats are immediately relieved. In a few cases, however, the temperature at first rises.

The effects on the E.S.R. are also diverse and not strictly parallel to the temperature changes. They may take the form of (1) a quick fall to normal, (2) a fall from very high to a lower range with a long period (6–12 months) before the readings finally settle, or (3) a slow lysis to normal from intermediate ranges extending over 4–6 weeks.

Blood-counts and hæmoglobin levels return to normal in a lag phase which closely follows the temperature record.

Concurrent with the effect of the drug on pyrexia, a subjective response, which, in a descriptive sense, w have termed the "detoxicating effect."

In contrast to the immediate effect on temperatur the gradual reduction in pulse-rate, which seems reflect accurately the course of the disease.

II. Effects on the Tubercle Bacillus

After some 17 days' adequate P.A.S. therapy ther a change in the appearance of acid-fast stained organi which often show striations, are sometimes beaded, a may be granular. At a time when many acid-fast ba may be demonstrated in direct or concentrated smea adequately controlled culture methods may yield only sparse growth or none at all. This observation has a been noted with streptomycin (Madigan et al. 1947). 21 out of 64 patients there was sputum conversion (t 13 of these had had active surgical treatment in additi to P.A.S.). The effect of P.A.S. on exudative infiltration a on endobronchitis, either with segmental collapse alo or collapse with tension cavitation, cannot be assessed this stage.

III. Toxic Effects

Of the 64 patients reviewed, 32 had nausea, and had nausea, diarrhœa, and vomiting. The shortest up lasted only two days whereas the longest lasted th months. These symptoms were not controlled by alk but appeared to be relieved by 10 minim doses of tinct

elladonna. Whether this gastro-intestinal action is uanical or pharmacological is still uncertain.

ıree cases of sensitisation to P.A.S. were observed. this was manifested by drug fever, with typical nting temperatures, the response after withdrawal g elicited by as little as 0·5 g. of P.A.S. Both were essfully desensitised with successive increments of ;. : the initial dose was 100 mg. daily for two days ; was raised to 200 mg. for two days, then 500 mg. wo days, 1·5 g. for four days, 3 g. for seven days, for seven days, 9 g. for seven days, 11 g. for seven ;, and so on. The third case of sensitisation presented generalised skin rash ; this was intensely irritating subsequently desquamated. Patch tests were positive ıspirin but not for P.A.S. The presumed sensitising en is acetylsalicylic acid or possibly salicylic acid, the allergic response is elicited to fixed antibody in skin by the near homologous P.A.S. hapten. The ıdilatation produced variable effects on the skin of and arms, only the fair-skinned showing true ıes. Some greasy skins and seborrhœic conditions e also been seen.

SITIVITY OF BACILLI TO P.A.S.: DEVELOPMENT OF RESISTANCE

trains of tubercle bacilli isolated before and after S. therapy were tested for sensitivity to P.A.S. Of 22 ins isolated before therapy all fell within the range ensitivity of 0·006–0·025 mg. per 100 ml. in a medium Dubos and Davis (1946), inoculated with 0·01 mg. per , after seven days' incubation. By comparison at the ne time the laboratory human strain, H37RV, was sitive at 0·006 mg., and CN844 at 0·025 mg. per 100 ml. 3 of the 5 patients from whom the organism could be overed immediately after 120 days' therapy its istance was found to have increased 50–100 times :

	Sensitivity (mg. per 100 ml.)				
	A	B	C	D	E
ore P.A.S. ..	0·012	0·012	0 012	0·012	0·012
er P.A.S.	1 6	0·8	0·05	1·6	0 05

contrast, the organisms recovered from 7 patients ated with sulphetrone during the period of more than) days in which they were exposed to P.A.S. were still sitive within the range of 0·005–0·05 mg. per 100 ml. P.A.S.

he slide test of Pryce (1941), recommended by Sievers 49), is well adapted for the detection of growth and the imation of drug-resistance. Sterile oxalated horse blood, ed 1 in 3 with distilled water, is a suitable medium, < $^1/_2$ in. glass microscopy slides are suitable mounts, and z. McCartney screw bottles are suitable containers. Bodyids are treated with 6% hydrochloric acid for 30 minutes 37°C and spun at high speed for a further 30 minutes. d the deposit is resuspended in sterile distilled water and eared ; or a first generation from a Lowenstein slope is spended in Dubos medium and smeared on the slide. Airying is followed by treatment with 6% sulphuric acid 5 minutes and thorough washing with distilled water. cubation at 37°C is for seven days.

EXPERIMENTS ON THE DETOXICATING EFFECT

It is widely believed that the extensive tissue destruction which characterises tuberculosis follows the conitioned hypersensitivity induced by the products of etabolism of virulent pathogens. The evidence for nplicating the diffusible protein component, thought be identical with tuberculin, is discussed by Brownlee 1948). That P.A.S. might exert its observed "detoxiating" effect by inactivating or otherwise interfering ith tuberculin hypersensitisation was the subject of the ollowing experiments on animals.

Forty-eight young adult guineapigs of either sex, eighing 350–400 g., were inoculated deeply into the right high muscles with 0·25 mg. of a fourteen-day-old subulture of human tubercle bacillus, strain CN844. The etails of diet and of animal management are those previously described (Brownlee and Kennedy 1948). By the end of the third week all the animals had palpable inguinal glands adjacent to the site of inoculation. In the fourth week 42 animals gave good positive reactions and 6 poor positive reactions to 0·00005 mg. of purified-protein derivative (P.P.D.) Old Tuberculin.

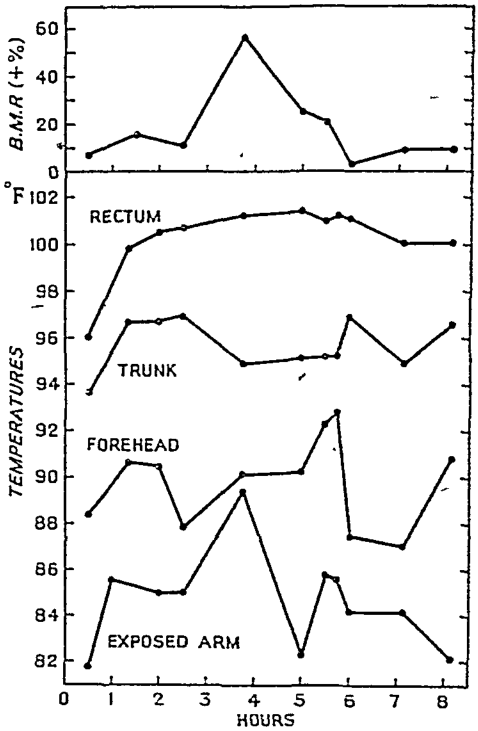

Fig. 2—Rectal and skin temperatures and B.M.R. in an untreated pyrexial tuberculous patient.

Exploratory Dosing Experiments with P.A.S.

In 5 tuberculous guineapigs the blood-P.A.S. levels an hour after they had received 90 mg. of P.A.S. (2 ml. of 4·5% solution) by mouth were 1·6 ± 0·4 mg. per 100 ml. Four hours later the same animals were given a further 90 mg. by mouth, and their blood-P.A.S. levels were 1·4 ± 0·5 mg. per 100 ml. 45 minutes after this dose.

Subsequently 17 tuberculous guineapigs were each given a single dose of 200 mg. of P.A.S. by mouth. Their blood-P.A.S. levels 30–85 minutes after dosing were 6·4 ± 4·4 mg. per 100 ml.

Preliminary Tuberculin-shock Experiments

The tuberculin used for these experiments was P.P.D. (batch T 2212 B) ; 156 mg. of this was dissolved in 6·5 ml. of N/50 sodium hydroxide and the pH adjusted to 8·5 with dilute phosphoric acid. The concentration was 12 mg. per ml. On the twentieth day after infection with tuberculosis 4 guineapigs were injected intraperitoneally with P.P.D. The guineapig given 10 mg. died within fourteen hours, and the one given 1 mg. was ill for two days ; those given 0·01 mg. and 0·1 mg. were unaffected.

On the twenty-first day after infection one animal injected intraperitoneally with 8 mg. of P.P.D. died within fourteen hours, that given 4 mg. was ill but survived, and that given 2 mg. died at seventeen hours. Two normal guineapigs injected intraperitoneally with 10 mg. of P.P.D. showed no ill effects and survived.

Main Tuberculin-shock Experiment

Thirty-three guineapigs now in the twenty-ninth day after infection remained for the main experiment, and these were divided into three groups.

Group 1 : eleven guineapigs were given P.A.S. 240 mg. by mouth and 25–42 minutes later were injected intraperi-

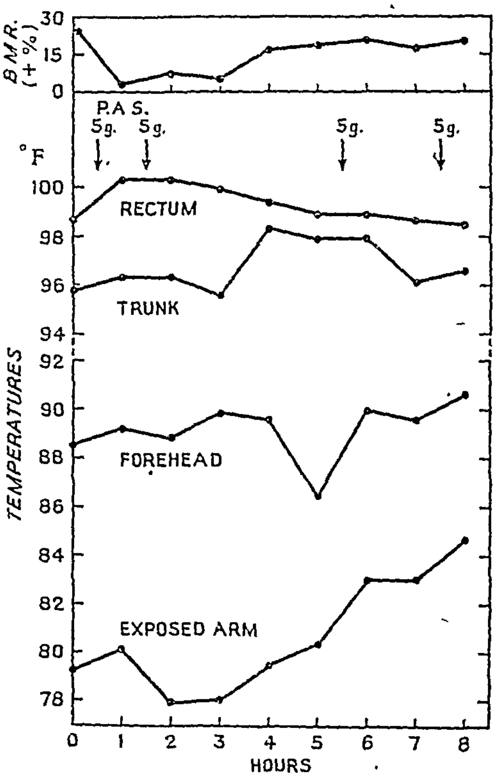

Fig. 3—Rectal and skin temperatures and B.M.R. in a pyrexial tuberculous patient given P.A.S. 30 g. in six divided doses daily, showing decrease in body (rectal) temperature and increase in skin-temperature.

toneally with 6 mg. of P.P.D.; this was followed 40–60 minutes later by a second dose of P.A.S. 340 mg. Eight guineapigs died within seven hours, and 3 within twenty hours.

Group 2: ten guineapigs were injected with a mixture of 100 mg. of P.A.S. and 6 mg. of P.P.D. which had been previously incubated for six hours at 37°C. Two died within six hours, 7 within twenty hours, and 1 which was ill was chloroformed after two days.

Group 3: twelve guineapigs were injected intraperitoneally with 6 mg. of P.P.D. Three died within six hours, 6 within thirty hours, and 3 which were ill were chloroformed after two days.

Conclusion

It may be concluded that a blood-P.A.S. level similar to that produced clinically does not protect the tuberculous sensitised guineapig from a lethal challenge dose of Old Tuberculin, P.P.D.; nor do previous admixture and incubation modify the challenge.

SKIN-TEMPERATURES AND B.M.R.

The observed peripheral vasodilatation in man given therapeutic doses of P.A.S., and the concurrent lysis of pyrexia, suggested that P.A.S. had a direct antipyretic effect.

Skin-temperatures were measured with previously calibrated constantan-copper thermocouples of large contact area, fixed tightly to the skin with openwork elastic strapping. The reference junction was held at 0°C by melting ice in a Dewar flask, and the potentials were read on a sensitive direct-reading millivoltmeter. The subjects were screened to prevent draughts, and the external temperature was carefully controlled. The basal temperature was provided by the rectal lead, and other leads were attached to forehead, trunk, and forearm.

Basal metabolic rates (B.M.R.) were estimated by calculation from indirect calorimetry with a closed air circuit in a Benedict-Roth apparatus. A respiratory quotient (R.Q.) of 0·82 being assumed, the normal values for oxygen consumption were calculated from tables (Sanborn 1922). The B.M.R. is expressed, as usual, as a percentage above (+) or below (−) the normal.

Control metabolism experiments on patients not receiving P.A.S. gave B.M.R. estimates within the range of + 7 to + 56%, with a mean of + 17% for ten estimations. The usual diurnal temperature sweep of the febrile tuberculous patient is accompanied by an increased B.M.R. (fig. 2). DuBois (1927) notes that the B.M.R. rises about 10% for each 1°C rise in body-temperature. Temperatures of forehead, arm, and trunk seem to follow the same pattern as the basal rectal temperature but show more fluctuation, probably because of imperceptible sweating.

This picture is modified by P.A.S. The effect of a single dose of 5 g. is to lower the body-temperature. The greatest effect is at about one and a half hours after P.A.S. has been given, a time at which blood-P.A.S. levels are highest (fig. 1). During the period in which the body-temperature is lowered there is a rise in the skin-temperature of the arm.

In febrile patients given P.A.S. during their waking hours the effects of the drug are least first thing in the morning when the patient wakes, and most last thing at night (fig. 3). In the case illustrated body-temperature fell progressively during the day but the skin-temperature progressively rose and the B.M.R. remained substantially unaltered. All febrile patients examined showed the same pattern of behaviour to P.A.S., but it should be emphasised that very variable records were made, of which fig. 3 illustrates an average experiment.

The record in the afebrile patient treated with P.A.S. is different (fig. 4). The body-temperature is maintained at a normal or slightly subnormal level, but there is raised skin-temperature and peripheral vasodilatation. In these patients, however, there is a well-marked increase in B.M.R.

It may be concluded that P.A.S. exerts a direct pharmacological effect, resulting in peripheral vasodilatation. This increases heat loss by direct radiation and is observed in both febrile and afebrile tuberculous patients. The increased heat loss in afebrile patients is compensated by an increase in B.M.R.

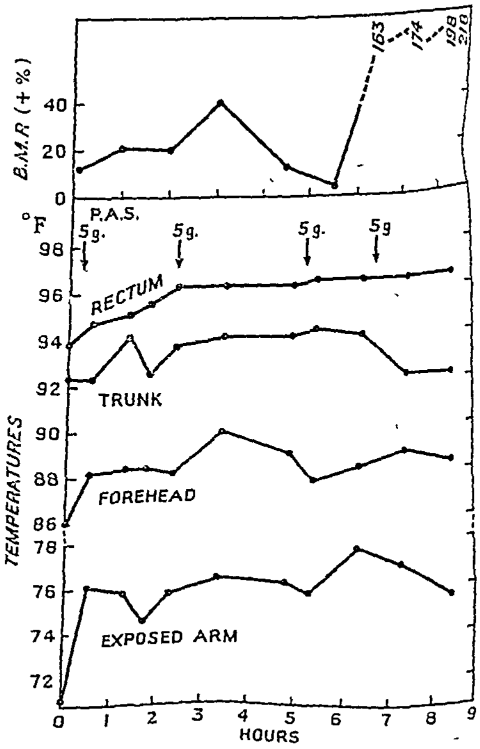

Fig. 4—Rectal and skin temperatures and B.M.R. in an apyrexial tuberculous patient given P.A.S. 30 g. in six divided doses daily, showing subnormal body (rectal) temperature, increased skin-temperature due to peripheral vasodilatation, and increased heat production shown by raised B.M.R.

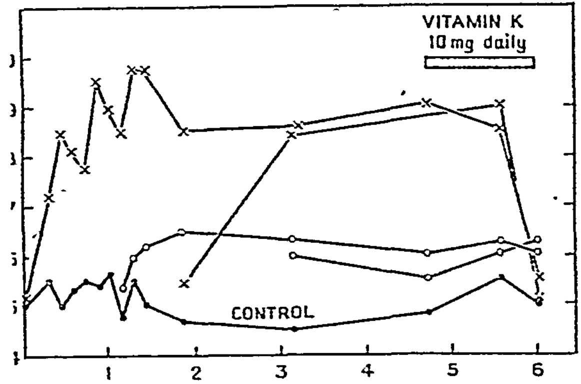

:—Prothrombin-times of whole plasma in tuberculous patients en P.A.S. 30 g. daily and in a control, showing prophylactic effect -cles) and therapeutic effect (crosses) of synthetic vitamin K mg. daily by mouth.

EFFECT OF P.A.S. ON PROTHROMBIN-TIME

tahmann et al. (1941), Huebner and Link (1941), Link et al. (1943) had demonstrated the anti-thrombin activity of dicoumarol, and have shown t this is due to the action of salicylic acid, a degrada- ı product. Salicylates and their derivatives were) found to prolong the prothrombin-time, an effect ich was reversed by synthetic vitamin K. We made . following experiment in an attempt to find whether › salicylic-acid derivative P.A.S. behaves in a like ınner.

Methods.—With but minor modifications the method of ick (1936) was used for estimating the prothrombin-time. iplicate estimates were made on (*a*) whole plasma, and plasma diluted to 12·5% with physiological saline solution, om freshly drawn oxalated whole blood. Dried human ain carefully stored at 0–4°C in wax-sealed containers was e source of thromboplastin, of which fresh extracts were epared for each series of estimates. The now well-appreciated ecautions of providing calcium-free tubes and pipettes, and using clean carefully washed serum-free pipettes for serum utions, were rigidly enforced. Shaking by rotation was efully controlled, particularly in estimates made with uted plasma. Control estimates, provided by healthy oratory staff, were included in each test, all of which were mpleted within five hours of collection of the blood.

Results.—Two series of experiments are recorded. The st (fig. 5) shows the prophylactic and curative effect vitamin K by mouth in doses of 10 mg. daily in versing the anti-prothrombin action of 30 g. of P.A.S. ily. Prothrombin-times are given for whole plasma. the second series randomised observations of pro- rombin-times in 29 patients under continuous therapy r at least two weeks were made (table II). The results r both whole and diluted plasma are given as deviations om the mean value of the controls. The increases in rothrombin-times are small and probably of no clinical gnificance (see below).

EFFECT ON GLOBULINS

Concurrently with the prothrombin tests, estimates Kunkel 1947) were made of the gamma-globulin content f each plasma. The findings are shown as deviations rom the normal (table II). Except in cases 9, 15, 19, nd 26, there was no significant deviation from the ıormal. The significance of these observations is discussed elow.

DISCUSSION

Detoxication

The term detoxication, though it must not be taken in its precise pathological meaning, conveniently describes the clinical effect which follows the exhibition of P.A.S. to the tuberculous patient. Subjectively, it is described as a feeling of well-being, and was observed in each of the present series—in the pyrexial, the apyrexial, and those who died. It has been noted by all clinical observers. It seems to be a specific effect analogous (for purposes of description) to a toxin-antitoxin neutralisation and of definite therapeutic value. We have failed to demonstrate its existence in animals, but our experiment by no means exhausts the possible mechanisms of action.

Much attention has been given in recent years to the rôle played by tuberculin in inducing the hypersensitive state which marks the collaboration of the tuberculous host in the death of his own tissue cells. A recent review of the evidence (Brownlee 1948) justifies the view that tuberculin-induced hypersensitivity ends the symbiosis between tubercle bacillus and host and ushers in the pathological changes of tuberculosis. The present animal experiment was designed to test the hypothesis that P.A.S. circulating in the blood-stream of the guineapig in the concentration deemed therapeutic for man (and guineapig) would chemically combine or otherwise neutralise lethal challenge doses of P.P.D. Old Tuberculin. This was not so; nor did previous admixture and incubation modify the score. The limitations of an experiment of this design are obvious, and only the negative aspect of the test is of value. We continue in the opinion that a reaction between P.A.S. and the products of metabolism of the tubercle bacillus, or of the induced biochemical lesions, remains to be demonstrated.

Antipyretic Action

Any analysis of the effect of P.A.S. on the fever of tuberculosis must explain the delayed antipyretic action and the apparent resolution by lysis. The classical picture of antipyretic action is provided by the coal-tar antipyretics, both in animal studies in which yeast or *Bact. coli* vaccine acts as the pyrogen (Brownlee 1939) and in human typhoid fever (Barbour 1921). Here, fall of temperature is by crisis in one to four hours. The less satisfactory response met in septicæmias generally, in

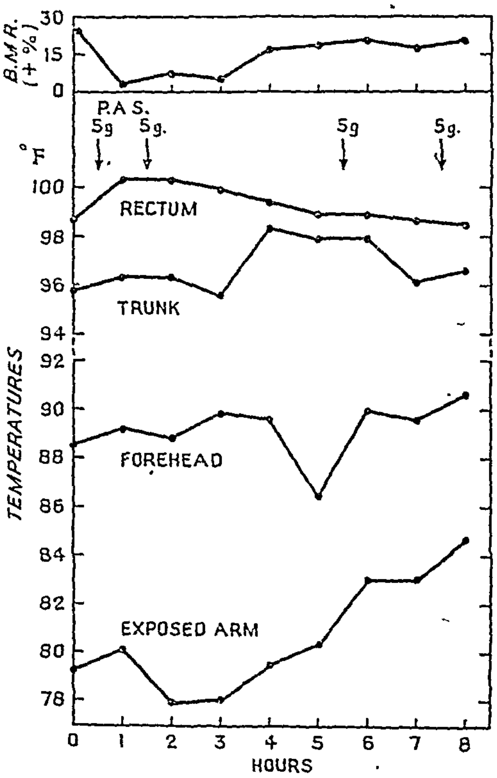

Fig. 3—Rectal and skin temperatures and B.M.R. in a pyrexial tuberculous patient given P.A.S. 30 g. in six divided doses daily, showing decrease in body (rectal) temperature and increase in skin-temperature.

toneally with 6 mg. of P.P.D.; this was followed 40–60 minutes later by a second dose of P.A.S. 340 mg. Eight guineapigs died within seven hours, and 3 within twenty hours.

Group 2: ten guineapigs were injected with a mixture of 100 mg. of P.A.S. and 6 mg. of P.P.D. which had been previously incubated for six hours at 37°C. Two died within six hours, 7 within twenty hours, and 1 which was ill was chloroformed after two days.

Group 3: twelve guineapigs were injected intraperitoneally with 6 mg. of P.P.D. Three died within six hours, 6 within thirty hours, and 3 which were ill were chloroformed after two days.

Conclusion

It may be concluded that a blood-P.A.S. level similar to that produced clinically does not protect the tuberculous sensitised guineapig from a lethal challenge dose of Old Tuberculin, P.P.D.; nor do previous admixture and incubation modify the challenge.

SKIN-TEMPERATURES AND B.M.R.

The observed peripheral vasodilatation in man given therapeutic doses of P.A.S., and the concurrent lysis of pyrexia, suggested that P.A.S. had a direct antipyretic effect.

Skin-temperatures were measured with previously calibrated constantan-copper thermocouples of large contact area, fixed tightly to the skin with openwork elastic strapping. The reference junction was held at 0°C by melting ice in a Dewar flask, and the potentials were read on a sensitive direct-reading millivoltmeter. The subjects were screened to prevent draughts, and the external temperature was carefully controlled. The basal temperature was provided by the rectal lead, and other leads were attached to forehead, trunk, and forearm.

Basal metabolic rates (B.M.R.) were estimated by calculation from indirect calorimetry with a closed air circuit in a Benedict-Roth apparatus. A respiratory quotient (R.Q.) of 0·82 being assumed, the normal values for oxygen consumption were calculated from tables (Sanborn 1922). The B.M.R. is expressed, as usual, as a percentage above (+) or below (−) the normal.

Control metabolism experiments on patients not receiving P.A.S. gave B.M.R. estimates within the range of + 7 to + 56%, with a mean of + 17% for ten controls. The usual diurnal temperature sweep of the tuberculous patient is accompanied by an increased B.M.R. (fig. 2). DuBois (1927) notes that the B.M.R. rises about 10% for each 1°C rise in body-temperature. Temperatures of forehead, arm, and trunk seem to follow the same pattern as the basal rectal temperature but show more fluctuation, probably because of imperceptible sweating.

This picture is modified by P.A.S. The effect of a single dose of 5 g. is to lower the body-temperature. The greatest effect is at about one and a half hours after P.A.S. has been given, a time at which blood-P.A.S. levels are highest (fig. 1). During the period in which the body-temperature is lowered there is a rise in the skin temperature of the arm.

In febrile patients given P.A.S. during their waking hours the effects of the drug are least first thing in the morning when the patient wakes, and most last thing at night (fig. 3). In the case illustrated body-temperature fell progressively during the day but the skin-temperature progressively rose and the B.M.R. remained substantially unaltered. All febrile patients examined showed the same pattern of behaviour to P.A.S., but it should be emphasised that very variable records were made, of which fig. 3 illustrates an average experiment.

The record in the afebrile patient treated with P.A.S. is different (fig. 4). The body-temperature is maintained at a normal or slightly subnormal level, but there is a raised skin-temperature and peripheral vasodilatation. In these patients, however, there is a well-marked increase in B.M.R.

It may be concluded that P.A.S. exerts a direct pharmacological effect, resulting in peripheral vasodilatation. This increases heat loss by direct radiation and is observed in both febrile and afebrile tuberculous patients. The increased heat loss in afebrile patients is compensated by an increase in B.M.R.

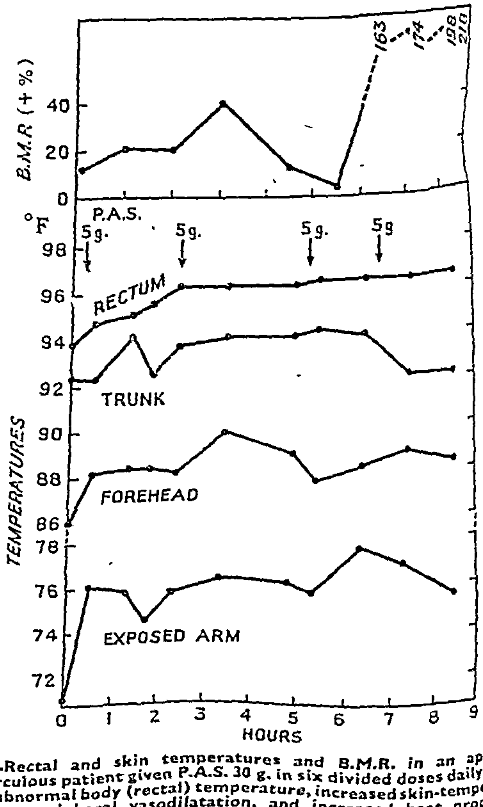

Fig. 4—Rectal and skin temperatures and B.M.R. in an apyrexial tuberculous patient given P.A.S. 30 g. in six divided doses daily, showing subnormal body (rectal) temperature, increased skin-temperature due to peripheral vasodilatation, and increased heat production shown by raised B.M.R.

py gave no evidence of impaired function. Cases 9, 19, and 26 did indeed yield evidence of significantly d titres. Case 9 is of great interest in that his current n, labelled chronic miliary tuberculosis, represents hird successful response to chemotherapy. The first n responded to rest, but the treatment was rounded with a course of gold therapy, as was the current ion. A breakdown two years later responded to hetrone, and during this period there was invasion secondary organisms. Cases 19 and 26 have also oured secondary invaders. No additional abnormal ure has been ascribed to case 15, and the cause of increased titre of gamma-globulins is not known.

r Side-effects

he further toxic effects reported have not been serious. hæmaturia seen by Nagley and Logg (1949) is pre- ably the result of crystalluria, due to the insoluble yl derivative of P.A.S. in acid urine, in which form ut 60% of the ingested dose is excreted (Way et al. 3). The difficulty does not arise in alkaline urine, and have not met it. The nausea, vomiting, and diarrhœa, n *persistent and frequently severe, which we observed* 2 out of 64 patients, has a high nuisance value and has sed the treatment to be abandoned in two other cases. ere is no complete antidote for the gastro-enteritis, alis, bases like magnesium trisilicate, and flavourings having failed. Belladonna relieves the vomiting but s not control the nausea; opium has been given to trol the diarrhœa when severe. About half of all tients receiving P.A.S. develop some intolerance to fatty ds. Three examples of sensitisation have been noted. o of these were of drug fever which responded to careful ensitisation. The third example was of an intensely ating generalised skin rash which quickly subsided withdrawal of P.A.S., and responded to desensitisation. original sensitising hapten may have been aspirin salicylic acid, and it must be supposed that the ginal antibody which was raised to these haptens was d by the skin. Rashes, probably of this kind, have n described by Hemming and Stewart (1949).

lue of P.A.S.

Though a final clinical assessment of our cases is not ng attempted at this stage, it may be asked why the ly promise seen in all cases is not sustained. Part of answer, we believe, lies in the direct pharmacological tion of P.A.S., which might in some cases be confused th a specific chemotherapeutic response. Nevertheless, is pharmacological response is valuable therapeutically. rt of the answer may also lie with the development of sistant strains at about the fourth month of therapy. e chemotherapy of tuberculosis seems to be evolving ng the line of a combination of drugs—streptomycin, lphetrone, and P.A.S.—to suppress the development of y single generation of drug-resistant organisms.

SUMMARY

The clinical description of "detoxication" is applied the immediate effect of P.A.S. therapy in the tubercu- us. Two pharmacological, as distinct from antibacterial, echanisms are involved. The first is thought to be ssociated with a direct action on the products of etabolism of the causal organism or on the biochemical sions it produces. It has not been identified. A blood- .A.S. level similar to that produced clinically does not rotect the tuberculous sensitised guineapig from a lethal hallenge dose of P.P.D. Old Tuberculin; nor do previous dmixture and incubation modify the effect of the hallenge. The second mechanism is an antipyretic ction due to peripheral vasodilatation. The heat loss s shown to be due to increased radiation associated with raised skin-temperature. Peripheral vasodilatation is lso seen in apyrexial patients, in whom heat losses re reflected in increases in B.M.R.

Changes in blood-counts, hæmoglobin, and E.S.R. estimates are secondary to the antipyretic effect. In contrast, improvements in the pulse-rate are not seen at this stage and are thought to indicate more accurately the course of the tuberculosis.

Of 22 strains of tubercle bacilli isolated before P.A.S. therapy all were inhibited from growth by 0·006–0·025 mg. per 100 ml. of Tween-albumin medium. After four months' treatment 3 of 5 strains showed an increase in resistance of 50–100 times, 2 strains growing in concentrations of 1·6 mg. per 100 ml. In contrast, cultures isolated from 7 patients treated for the same period with sulphetrone and P.A.S. were still sensitive to 0·005–0·05 mg. of P.A.S. per 100 ml.

After daily doses of 30 g. of P.A.S. a prolongation of blood-clotting time occurs within a few days; this is not cumulative, and is maintained throughout the course. The administration of 10 mg. of synthetic vitamin K daily by mouth prevents its onset, and the same dose is therapeutic. The greatest prolongation obtained on whole plasma was 22 seconds, which is equivalent to 32% prothrombin on our composite dilution curve. This is not clinically significant, unless there is concomitant liver disease or surgery is contemplated, when vitamin K should be given.

Simultaneous estimates of gamma-globulins gave no additional evidence of liver dysfunction.

Serious toxic effects have not been encountered, but the nausea, vomiting, and diarrhœa observed in 22 of 64 patients given the sodium salt of P.A.S. have a high nuisance value. No complete antidote is known.

Three drug sensitivities, two of drug-fever and one of generalised desquamating skin-rash, responded to desensitisation.

The clinical results of administering P.A.S. to 64 patients is summarised.

The animal experiments were made by G. B. with Mr. C. R. Kennedy, to whom our thanks are due. Our thanks are also due to Sister Clancy and the nursing staff of the unit.

pneumonia, and in tuberculosis (Cushny 1947) is often forgotten. A re-examination of temperature records in patients given P.A.S. during waking hours (fig. 6) shows that, in fact, the antipyretic action does appear within two or three hours, but, because of the scheme of dosing usually followed, the first fall is often masked by a preliminary rise of temperature. The evidence that an abnormal amount of heat is still being produced by the body is provided by the records of the skin-temperatures of trunk or arms. At the times when the body-temperature, as measured by rectal thermometer, is falling, there is a corresponding rise in the skin-temperature of trunk or arms. We are satisfied that the consequent increase in heat loss is sufficient to balance the lowered body-temperature. Thus, the antipyretic effect follows from a direct drug action on heat-regulating centres, and not in the first instance, by causing metabolic changes or by interfering with the production or action of toxin. It is remarkable that the antipyretic effect of P.A.S. is unaccompanied by perceptible sweating. Indeed we believe this valuable property alone would ensure a place for P.A.S. in the management of tuberculosis. In the present series only one patient visibly sweated, and in this case complications were present. The reasons for this property of P.A.S. have not emerged from the present study.

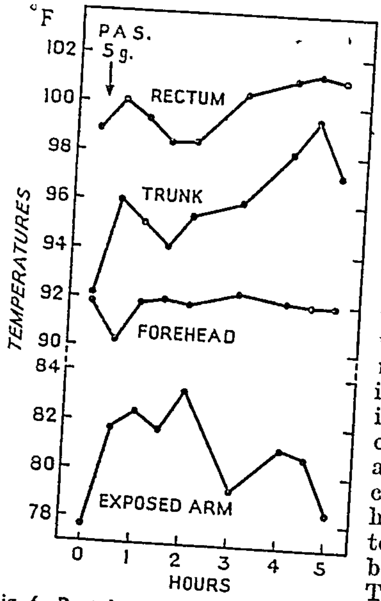

Fig. 6—Rectal and skin temperatures in a pyrexial tuberculous patient, showing fall of body (rectal) temperature while blood-P.A.S. level is highest (see fig. 1); during this time the peripheral vasodilatation is greatest and the exposed arm is radiating most heat.

An anomalous antipyretic effect of P.A.S. is observed in apyrexial patients. Unlike other antipyretics, P.A.S. causes in these cases a sufficient loss of heat by vasodilatation to lower the body-temperature by 2°F or more. The heat loss may be great enough to cause significant changes in B.M.R. Three possible explanations may be put forward : (1) that P.A.S. can so affect the "control" cells of the heat-regulating centre that the "thermostat" is set for a new low range ; (2) that P.A.S. stimulates vasodilatation by acting at a level below the hypothalamus and independently of the heat-regulating centre ; and (3) that the heat-regulating centre has been rendered unstable by long-continued toxic repression and reacts erratically to stimulation—in the words of the usual analogy, the range of the "thermostat" has been increased. We favour the last hypothesis.

Measurement of B.M.R.

Several aspects of the measurement of B.M.R. in tuberculous patients call for comment. We have already noted that control metabolism experiments on similar patients who were not receiving chemotherapy yielded B.M.R. estimates of + 7 to + 56 with a mean of + 17 for ten patients. All the patients were confined to bed from the evening before, but were allowed normal movement except for the limitations imposed by the length of the thermocouple leads. Our satisfactory control figures are in accord with the data of Robertson (1944) and Rabinowitch (1944) ; they are, however, in well-marked contrast with our own experience of "casual" B.M.R. estimates made in short-term hospital patients. T explanation for the steady base-line provided by tub lous patients may lie in their familiarity with ex- mental procedures. They are, moreover, in familiar friendly surroundings.

Changes in Blood

The several changes in the distribution of the for blood elements, in hæmoglobin concentration, and that aspect of E.S.R. which does show a return to nor seem to be secondary to the remission of fever result from antipyretic action. They are none the less val

Bacteriostasis

Observers mostly agree that human and bovine stra of tubercle bacilli are inhibited from reproduction favourable media in vitro by the incorporation of co centrations of P.A.S. ranging from 0·005 to 0·05 mg. p 100 ml., depending on the media used and the amo of the inoculum. In the present series, the inhibiting concentrations of 22 strains isolated before th were all between 0·006 and 0·025 mg. per 100 ml. u the conditions of the test. After four months' therap of 5 strains which were recovered immediately sho an increase in resistance of 50–100 times, 2 of the stra growing definitely, though slowly and sparsely, in c centrations of 1·6 mg. per 100 ml. In contrast, organisms isolated from 7 patients treated with sulp trone during the period of exposure to P.A.S. were sensitive within the range of 0·005–0·5 mg. per 100 of P.A.S. These observations are essentially simila those of Delaude et al. (1949), who found that cult isolated from 4 of 5 patients treated with P.A.S. 157–251 days could grow in concentration of P.A.S. 1·6–6·4 mg. per 100 ml. of medium. This increa resistance was not seen in cultures from patients w had received streptomycin and 'Promin' in additi

Prothrombin-time

In view of the adverse effect of dicoumarol, salicylates and acetylsalicylic acid on liver function, the adminis tration of P.A.S. 30 g. daily for periods measured in un of three months implies certain hazards. The prolonga tion of the clotting-time in the present series is substantial and statistically significant. However, serial estimations made at regular intervals for three and four months showed no evidence of a cumulative effect. Indeed it has been a constant feature that the increase of the prothrombin-time, which occurs within a few days inception of P.A.S. therapy, is maintained with m fluctuations throughout. The greatest prolonga obtained on whole plasma—i.e., 6 seconds—correspon to a prothrombin-time of 22 seconds, a figure which equivalent to 32% prothrombin on our composite dilut curve derived from six normal plasmas. Spontane hæmorrhages do not, in our experience, occur w prothrombin concentrations in excess of 15%. Howev the risk of such an occurrence must be increased wh there is concomitant liver disease, such as cirrhosis amyloid disease.

As with other salicylates, the simultaneous administra tion of synthetic vitamin K prevents the prolongat of prothrombin-time. Usually a simultaneous daily do of 10 mg. by mouth prevents it completely, and th same dose, used therapeutically, will produce a gra return to a normal clotting-time within eight da Apart from considerations of concomitant disease, th clinical significance of the prolonged clotting-times seem to be slight. However, where these considerations apply or where surgery is contemplated, simultaneous prophy lactic therapy with vitamin K is an obvious precautio

Globulins

In so far as production of globulins may be accepted as an index of liver function, 29 patients receiving P.A.S.

n unable to find any reports supporting immediate trectomy for this sequence, which, as we have noted, quite rare. Our own case is an example of the rewards ich radical surgery offers under suitable operating ditions.

n contrast, postoperative hæmorrhage affords an portunity for deliberate consideration about the isability of further operation, though, as in our t case, undue procrastination may prove fatal. The y replacement by modern methods of blood-transfusion, reluctance to advise a major operation soon after the ergency procedure, and foreknowledge of the possible iculties of the resection may blind the surgeon to the h mortality of conservative treatment. At the West ddlesex Hospital it is believed that an early gastrectomy he operation of choice; 2 of our cases treated by this thod had a smooth and uneventful recovery, whereas third, who received transfusions equivalent to nearly times his circulating blood-volume, deteriorated wly and progressively until his death.

CASE-RECORDS

Case 1.—A man, aged 46, was admitted to the West ddlesex Hospital on June 2, 1949. For many years he l had epigastric pain on and off after meals. His dyspeptic acks were treated by intermittent and perfunctory dosage h powders, and, while severe enough to cause the loss several working days in the year, they had never been rsistent and frequent enough to lead to a diagnostic restigation. During the last fortnight the pains had own worse, culminating in a violent and protracted paroxysm iich led to his admission to hospital.

On examination, the grunting respirations, the general pression of agony, and the exquisitely tender board-like dominal wall made the diagnosis obvious, though severe ock and a cachectic appearance gave cause for comment.

Operation was undertaken two hours after admission and ne hours after perforation, by which time restorative easures had improved his general condition. A perforated ronic gastric ulcer was closed with an omental graft and e abdomen closed without drainage. His convalescence rsued an uneventful and satisfactory course until the nth postoperative day, when he complained of a "catch the chest," *coughed up bloodstained sputum, and pre*nted the signs of dry pleurisy which in a day or two were ansformed into those of a small effusion.

This incident, trivial in itself, altered the whole course of s illness, by focusing attention on his chest instead of his omach; the short period when a radical intervention ight have been successful was therefore allowed to pass, d he never thereafter appeared fit enough to survive a astrectomy. He continued to bring up—or, as we then ought, to cough up—frothy blood, and a melæna stool duced his hæmoglobin sufficiently to demand a transfusion. mprovement was then rapid, no further blood or melæna ppeared, and the condition of his chest gave no cause for larm. Suddenly, on the twentieth day after operation, a iolent hæmatemesis nearly ended his life and he was only estored by a massive transfusion.

The subsequent course of his illness showed progressive leterioration, punctuated by dramatic episodes in which ppalling blood-losses were barely made good by repeated ransfusions. Though the man's condition improved remarkably after each blood-replacement, it became evident that e could not withstand these repeated circulatory shocks ndefinitely, and on July 11, thirty-eight days after his operation, he succumbed to a final profuse hæmatemesis. During this period he received no less than 46 pints of blood n addition to several pints of glucose-saline and plasma.

Necropsy disclosed that the ulcer had eroded the splenic artery.

Case 2.—A man, aged 51, was admitted to the medical wards for investigation of intermittent dyspepsia of two years' duration. Radiographic examination showed a large penetrating ulcer on the lesser curvature of the stomach. Three days after this examination he started a profuse hæmatemesis, and four days later, while the bleeding still continued, the ulcer perforated.

At operation, a large prepyloric ulcer with a small anterior perforation was found. An immediate partial gastrectomy was followed by an uneventful recovery.

The specimen showed an extensive prepyloric ulcer with a perforation anteriorly and an eroded vessel posteriorly.

Case 3.—A man, aged 43, had a nine years' history of dyspepsia, and elsewhere duodenal ulceration had been diagnosed. Sudden violent pains led to his admission, and the expected perforation was closed six hours after its onset.

Progress was satisfactory until the thirteenth postoperative day, when a large hæmatemesis occurred. His condition grew rapidly worse despite transfusion of 6 pints of blood, and eighteen hours after the onset of bleeding partial gastrectomy was performed; satisfactory recovery followed.

The specimen showed a prepyloric ulcer with an anterior perforation; the floor contained an eroded branch of the right gastric artery.

SUMMARY

Perforation and hæmatemesis form an uncommon but dangerous combination.

The event may usually be ascribed to an extensive single ulcer or to two separate lesions.

The best recovery-rate is likely to follow immediate partial gastrectomy.

Three cases are described, 2 of which were successfully treated by resection.

The two successful gastrectomies were performed by Mr. W. J. Ferguson, and I wish to thank him for allowing me to use the case-records and for much helpful advice.

SOME OBSERVATIONS ON ANTIGEN-ANTIBODY REACTIONS

F. STRATTON
M.D., B.Sc., D.P.H.
REGIONAL TRANSFUSION OFFICER, MANCHESTER; SPECIAL LECTURER IN HUMAN SEROLOGY, UNIVERSITY OF MANCHESTER

THE antigen Rh is present on the surface of erythrocytes from Rh-positive people. It was noticed that sometimes the reaction between Rh antigen and the corresponding antibody was not followed by erythrocyte agglutination; in fact, the erythrocytes were apparently unaffected. The Rh antibodies in such cases were referred to as incomplete antibodies (Race 1944). That the union of Rh antigen and antibody had taken place was demonstrated by the use of anti-human rabbit serum (Coombs et al. 1945), commonly known as Coombs reagent. When a suitably prepared anti-human rabbit serum was added to Rh-positive cells that had previously been acted upon by Rh incomplete antibody, cell agglutination resulted.

It has been previously shown that this phenomenon is not confined to the Rh antigen-antibody system, but has a more general application. This paper describes a further extension of the principle involved, which has been studied in relation to sheep cells treated with a sheep-cell hæmolysin prepared in rabbits and an anti-rabbit hen serum.

METHOD AND TECHNIQUE

Three hens about 12 months old were injected intramuscularly with 5 ml. of alum-precipitated rabbit serum and reinjected a month later. They were bled 10 and 18 days after the second injection. Serum P (IV) taken from hen P on the 18th day was found to be the most suitable of the three and was used in most of the experiments.

PERFORATION AND HÆMATEMESIS

LOUIS A. IVES
M.B. Lond., F.R.C.S.
SURGEON, ST. CHARLES' HOSPITAL, LONDON; LATE CHIEF ASSISTANT IN SURGERY, WEST MIDDLESEX HOSPITAL, ISLEWORTH

SEPARATELY, perforation and hæmatemesis are everyday complications of gastric and duodenal ulceration, but together they are much less common and many experienced clinicians have not encountered an example. Indeed, the rarity has occasioned the aphorism: "Perforated ulcers do not bleed and bleeding ulcers do not perforate." Writings on the subject are scanty, and advice about treatment practically non-existent, but the prevailing impression is that the outlook is gloomy whatever is done. Since we had three cases in our unit at the West Middlesex Hospital, two of which were saved by bold surgical treatment, a review of the condition and an account of our experiences may be of value.

INCIDENCE

It appears that hæmorrhage in sufficient amount to cause anxiety follows perforation in about 1–2% of cases. James and Matheson (1934) described 2 examples in 75 cases at the Central Middlesex Hospital; and Forty (1946) reported one hæmatemesis following operation in 100 consecutive perforations. In a series of 240 perforations collected by Eliason and Ebeling (1934), 4 bled postoperatively. On the other hand, Raw (1944) did not meet with this complication in 312 personal cases of sutured perforation, and Finsterer (quoted by Winters and Egan 1939), in his extensive experience of gastric surgery, found perforation and hæmorrhage occurring together on only 3 occasions.

The reverse sequence—hæmatemesis followed by perforation—is probably still more uncommon. Hurst and Ryle (1937) found 1 perforation in 82 cases of severe hæmatemesis, and in 361 cases collected by Winters and Egan (1939) no less than 23 patients perforated within fourteen days of their last hæmorrhage; but most observers would regard hæmatemesis followed by perforation as a very rare event. Among the large number of hæmatemesis patients treated in the medical wards of this hospital in the last ten years, only one has perforated while under treatment.

PATHOLOGY

Most of the ulcers which perforate are on the anterior aspect of the duodenum or lesser curvature of the stomach, in which situation the larger arteries in the neighbourhood are protected from the erosive proclivities of the ulcer. On the other hand, posteriorly placed lesions may open up a vessel, but tend to burrow into a solid viscus rather than penetrate into the abdominal cavity. The margin of the perforation does not bleed because the adjacent vessels are obliterated by endarteritis and thrombosis. This occurs so uniformly as to eliminate the perforation itself as the source of the hæmorrhage, although in a unique case of simultaneous perforation and hæmorrhage encountered by R. L. Galloway (personal communication) an artery in the edge of the perforation bled vigorously and not only the stomach but the abdominal cavity was full of blood.

An attempt has been made to distinguish ulcers which bleed from those which perforate, on the basis of their morbid anatomy, and Behrend (1930) suggested that perforation occurs in the chronic type of ulcer with a sclerotic base, while hæmorrhage is more prone to complicate the acute ulcer with soft congested edges. It is true that severe and even fatal hæmorrhage may result from an acute ulcer, but the sclerotic variety is not immune, and in most of our urgent gastrectomies for hæmatemesis a chronic indurated lesion ha present. It is the situation rather than the type of which determines whether its active invasion will in perforation or in hæmorrhage.

It is apparent from a study of our own and reported cases that when hæmorrhage and perfor occur in the same patient either a single ulcer grown so large as to involve both anterior and po aspects of the stomach or duodenum, or else mu lesions are present. In the case reported by Hurst Ryle (1937): "A perforation which would admi tip of the little finger was seen on the anterior s of the duodenum. Almost the entire surface of duodenum was occupied by a chronic ulcer one by half an inch. On the floor a vessel had been compl divided." In each of our own cases there was a sol gastric ulcer of such dimensions that perforation occurred anteriorly and vascular penetration posteri

Kaye (1946) reports a case of double gastric with perforation and hæmorrhage. A prepy foration had been sutured; six days later a h hæmatemesis occurred which led to the patient's de and necropsy revealed an unsuspected ulcer on the l curve of the stomach.

In the 2 cases of James and Matheson (1934) perforations were in the duodenum, the hæmorrha each instance originating from an unsuspected s ulcer in the stomach. They suggest that prud would dictate examination of the stomach for a s ulcer when operating for perforation, and Winters Egan (1939) comment that hæmorrhage following su repair of a perforation should arouse suspicion another ulcer may be responsible for the bleeding.

The case reported by Monti (1946) is inte as a museum piece. A middle-aged man perf after a large hæmatemesis. At operation the p tion was found in the posterior stomach wall, nearby a nodular tumour, the size of an adult was evidently the source of the hæmorrhage. mortem the growth was secured for section, and p to be a neurinoma.

MORTALITY

The general belief that the syndrome is attended a high mortality is supported by the meagre statis available. Hamilton Bailey (1944) records 3 de from hæmatemesis in 118 sutured perforations. K patient died, as did the one under the care of H and Ryle; and both cases in James and Mathe series died. The solitary example described by appears to have survived without further su treatment, and R. L. Galloway's case was brought successful conclusion after an immediate resection our own series 1 patient treated conservatively di survive; the other 2 recovered after an emer gastrectomy.

TREATMENT

When perforation succeeds hæmatemesis, the nec for operation is not in doubt and the choice lies be simple closure of the perforation and a more amb intervention designed at once to deal with the perfo and control the bleeding. A partial gastrectomy these requirements and will ensure that multiple are not overlooked—visual examination of the st and palpation of its wall can be an unreliable met locating a bleeding gastric ulcer, particularly an one (Ives 1949). Though we regard immediate res as the ideal operation, circumstances may sugge lesser procedure, for many perforations are dealt in the small hours when a skilled team is usuall available. If continuing hæmorrhage does not re to transfusion, a planned resection may be carrie in the confident assumption that the risks of ope are outweighed by the dangers of further delay. I antibody system, and especially to see whether it ld be of any practical value. It must be emphasised once that the reagents in the sensitised-sheep-cell i-rabbit hen system are much weaker than in the esponding Rh anti-human rabbit system. Nevertless, the reagents used in this work could be made to clear-cut results provided that the right quantities e used. Once an immune hen serum has been absorbed standardised against a particular mixture of sitised sheep cells, the experiments may only be done h that particular serum using those particular test s.

he results are interesting since they show clearly t an immune hen serum can be prepared which will lutinate sensitised sheep cells, and that this activity pecifically prevented by rabbit serum but not by rat uman serum. Comparing this result with that in the nan Rh system, it seems that under certain conditions hæmolysin present on sheep cells gives reactions ilar to those of an incomplete Rh antibody absorbed to human cells. In fact, the latter state of affairs hat present in a baby affected with hæmolytic disease ere the erythrocytes are undergoing hæmolysis. It is eresting to note that, as far as it was possible to ermine, complement will still cause the lysis of sensied sheep cells which have been massively agglutinated immune hen serum.

When suitably absorbed anti-rabbit hen serum is owed to react with Rh-positive human cells sensitised th incomplete Rh antibody, agglutination occurs. is reaction is prevented not only by rabbit serum but human serum also. The addition of human serum mmune hen serum does not, nevertheless, prevent the ction of the immune hen serum with sensitised sheep s.

lthough proper quantitative evaluation is difficult, se and other observations seem to indicate that a tem of this nature (sensitised-sheep-cell immune serum) is fairly specific for the animal serum cerned—in this case rabbit serum. It is much more cific, for example, than the precipitin test.

The final experiments seemed to show that rabbit tibody absorbed on to human cells is detectable by ng this system. Control samples designed to give glutination in the presence of normal rabbit serum inly failed to show absorption of the immune hen um; but the technique was difficult, and especially control (5) it was not easy to prevent non-specific sorption. Nevertheless, the results were quite clear t.

Rat serum failed to prevent the reaction in the diluns used, and this leads to the hope that this system ay be of value in the study of experimental nephritis here an anti-rat-kidney antibody prepared in rabbits used. This latter work is proceeding in coöperation ith Dr. M. H. Roscoe of the Department of Medicine, anchester University.

SUMMARY

A method is described of using an immune hen rabbit rum with sensitised sheep cells as an indicator to detect bbit serum. The test is shown to be specific.

Using a well-known hæmolysin, like the sheep-cell ne, it can be demonstrated that when sensitised sheep ells are suspended in a suitable antiserum the reaction one of agglutination, and this is compared with the gglutination by Coombs reagent of the sensitised rythrocytes from a baby with hæmolytic disease of the ewborn.

This system may be useful in the detection of rabbit erum absorbed on to the tissues of another animal.

ARTHRITIS MUTILANS ASSOCIATED WITH PSORIASIS

OWEN CLARKE
M.A., M.D. Camb.
MEDICAL ADVISER TO THE ONTARIO GOVERNMENT IN THE UNITED KINGDOM

THE association of psoriasis with rheumatoid arthritis was first noted by Alibert in 1822, and Bourdillon (1888) suggested the possibility of a common ætiology. Since then, numerous cases have been described, and criteria have been put forward in order to limit the title "psoriasis arthropica" to a specific condition, thereby avoiding its use in cases where the two conditions may be associated by chance.

The interest in the present case lies as much in the extent of the destruction of the bones of hands and feet as in the association of psoriasis with arthritis mutilans.

CASE-RECORD

A man, aged 63, was first seen in May, 1949, when the abnormal condition of his hands (fig. 1) and feet (fig. 2) was noted. In the 1914–18 war he served as a regular soldier and received a gunshot wound of the left forearm, for which he was subsequently invalided from the Service. As can be seen in the X-ray film (fig. 1), there is an ununited fracture of the left ulna, and some fragments of metal remain in the forearm. However, at present the movements of the wrist are full and strong, and the importance of this injury rests in the fact that because of it a thorough physical examination was done to assess Army pension. It is therefore certain that in 1921 there was no evidence of disability in the hands or feet. The patient says that the arthritis of his hands and feet came on between about 1925 and 1930. The onset was fairly rapid, with pain and stiffness of the hands and considerable difficulty and discomfort on walking. The only treatment adopted was local heat and liniments, and in due course the pain became steadily less, but the deformity of the hands and feet increased. The patient thinks that the condition has been stationary since 1930, and he has continued his work as odd-job man and gardener without much difficulty.

The patient first noted his skin disease about 1932–34, when it started on his hands and forearms; it has since spread to cover most of the trunk, buttocks, and limbs, the face being spared. Seventeen years ago psoriasis was diagnosed and chrysarobin ointment was applied. The patient has steadily continued with this ointment, but there was little improvement until he recently changed to soap and water. There have not been any associated fluctuations in the joint and skin conditions.

On examination there is very little voluntary movement in the fingers or thumbs, apart from an ability to oppose the thumb for a grip. Some fingers can be stretched about $^1/_2$ inch and rebound into their usual positions. The patient can dress himself, including tie, bootlaces, and important buttons, he can use the implements of his trade and of the table, and he is not particularly distressed by his condition. He has no serious disability of the other joints of the limbs or of the spine. Movements are strong at the elbows and wrists. Sensation to pinprick and cotton-wool is normal over his hands and feet. The upper-limb reflexes are brisk and equal, the lower-limb reflexes sluggish but equal, and the plantar responses flexor on both sides. Blood-pressure 150/90 mm. Hg. The vessel walls are thickened, but good pulsation is felt at the wrists and over the dorsum of each foot. The skin temperature of hands and feet is normal. The trunk, buttocks (fig. 3), and limbs are covered with psoriasis, and the nails are pitted.

Radiography.—There is remarkable similarity in the condition of the hands and feet, with gross destruction and absorption of the proximal and middle phalanges of all digits; in many cases only a small fragment of bone remains between metacarpal and terminal phalanx. The terminal phalanges are relatively intact, though rarified. The metacarpal bones have been damaged at their distal ends, and are deformed and distorted, but show little rarefaction. The 4th and 5th right metacarpals are mostly absorbed, and the distal end of the right first metacarpal has undergone absorption and bending. The metatarsals are less affected but show tapering of the distal ends. Though the carpometacarpal and tarsometatarsal joints are not distinct, except in the left hand, the small bones and joints of the wrists and ankles are clearly defined. The musculature of the

The anti-rabbit hen serum was inactivated by heating at 55–56°C for 30 minutes and then diluted 1 : 2 with physiological saline solution and absorbed at room temperature with washed packed normal sheep cells followed by washed packed rabbit cells. The reagent was tested against sheep and rabbit cells as described below, and if the absorption was complete it was considered ready for use. Normal hen serum diluted 1 : 2 was inactivated and absorbed in the same way.

Sheep cells were prepared in a 10% solution and sensitised with five minimal hæmolytic doses of anti-sheep-cell hæmolysin. (The hæmolysin used should be of high titre and free from agglutinin at this dilution.) The sensitised sheep cells and normal sheep cells were then washed three times with normal saline and resuspended as 10% suspension in normal saline. These reagents were now compared and were considered satisfactory if the sedimentation-rates of both were the same and there was no microscopic evidence of agglutination in the sensitised sheep cells.

Agglutination tests were carried out on microscope slides at room temperature. One volume of serum or of saline red-cell suspensions was used in the test. Titrations were done by doubling the serum dilutions using normal saline as diluent; one volume of test cells was then added. Macroscopic evidence of positive agglutination was noted, but absence of agglutination was confirmed microscopically. The time of agglutination was taken, and about 4–10 minutes was allowed before a result was pronounced negative, depending on the sensitivity of the sheep-cell hæmolysin mixture. Aggregation of the erythrocytes was assisted by the gentle agitation and mixing of the cells and sera equally in tests and controls.

Very large aggregate.	Few free cells	= + + +
Large aggregate.	Few free cells	= + +
Small aggregate.	Many free cells	= +
No agglutination		= Neg.

EXPERIMENTS

For convenience the reagents prepared as described above will be denoted by abbreviations as follows :

Anti-rabbit hen serum = P (IV)
Normal hen serum = N.H.S.
Sensitised sheep cells = S.S.C.
Normal sheep cells = N.S.C.

In the first group of experiments it was found that sensitised sheep cells were agglutinated by absorbed anti-rabbit hen serum P (IV) :

(1) P (IV) + S.S.C. = + + +
(2) N.H.S. + S.S.C. = Neg.
(3) P (IV) + N.S.C. = Neg.
(4) N.H.S. + N.S.C. = Neg.
(5) Saline + S.S.C. = Neg.
(6) Saline + N.S.C. = Neg.

In the second group of experiments it was found that normal rabbit serum diluted 1 : 20 would prevent the reaction between absorbed immune hen serum P (IV) and sensitised sheep cells. Here one volume of 1 : 20 normal rabbit serum was added to one volume of P (IV) and mixed at room temperature, and one volume of sensitised sheep cells was added to the mixture. In the control test an equal volume of saline was used :

(7) P (IV) + 1 : 20 normal rabbit serum + S.S.C. added after mixing = Neg.
(8) P (IV) + normal saline + S.S.C. added after mixing = + + +

These basic tests and their respective reactions, 1–8 inclusive, had to be undertaken on each occasion with the results as given above, before conducting any further experiments.

The serum P (IV) was next titrated in two ways : first it was tested in serial dilutions against sensitised sheep cells, and secondly it was tested undiluted against serial dilutions of normal rabbit serum to find the greatest dilution of rabbit serum which would just prevent its *agglutination* of sensitised sheep cells.

Test cells	*Dilution of serum P (IV)* 1:4	1:8	1:16	1:32	1:64	1:128	1:2
S.S.C. ..	+ + +	+ + +	+ + +	+ +	?	Neg.	Neg.
N.S.C. ..	Neg.	Neg.	Neg.	Neg.	Neg.	Neg.	Neg.

Test cells	*Dilutions of normal rabbit serum with the addi each of an equal volume of P (IV)* 1:200	1:400	1:800	1:1
S.S.C. ..	Neg.	+ + +	+ + +	+ + +

It will be seen that the reagent had a titre of 32 and w inactivated by an equal volume of 1 : 200 normal rab serum.

Subsequently, sera from humans and rats we examined to determine whether they would prevent t immune hen serum from clumping sensitised she cells. Equal volumes of all the reagents were u The results were :

P (IV) + saline + S.S.C. = + + +
P (IV) + 1 : 100 rabbit serum + S.S.C. = Neg.
P (IV) + 1 : 20 rat serum + S.S.C. = + + +
P (IV) + 1 : 20 human serum + S.S.C. = + + +

P (IV) immune hen serum had already been absorbe with sheep and rabbit cells and was now further absorbed with human cells (P (IV) Hu.). Similarly, normal he serum was absorbed with human cells as well as she and rabbit ones (N.H.S. Hu.) as described above.

Sensitised human cells were prepared by saturating human group-O Rh-positive erythrocytes with incom plete Rh antibody, then washing the cells three time with saline. The following tests were then made, eq volumes of reagents being used :

P (IV) Hu. + group-O . . . = Ne
P (IV) Hu. + group-O . = + + +
N.H.S. Hu. + group-O . sensitised human cells = Ne

P (IV) Hu. serum was then mixed with an eig of its volume of normal human serum and this mixt divided into two parts and tested. Equal volume reagents were used. The results were :

Mixture + S.S.C. = +
Mixture + group-O Rh-positive sensitised human cells = N

P (IV) Hu. serum was also mixed with an eight its volume of normal rabbit serum and this mixture divided into two parts and tested as above. Result

Mixture + S.S.C. = Ne
Mixture + group-O Rh-positive sensitised human cells = Ne

It was finally decided to try to determine wheth rabbit antibody could be detected if it was absorb on to, or united with, an antigen or protein on a tis from different species of animal. For this purpo group-A Rh-positive human erythrocytes were sensitise with an absorbed incomplete Rh antibody of huma origin. These cells were then washed three times wi normal saline. To two volumes of these packed ce were added :

(1) 2 volumes of absorbed undiluted anti-human rabbit ser (Coombs reagent).
(2) 1 volume normal rabbit serum + 1 volume anti-A agglutinat serum.
(3) 2 volumes normal rabbit serum.
(4) 2 volumes anti-A agglutinating serum.

A further test was done by mixing 2 volumes of nor washed cells with Coombs reagent, viz. :

(5) 2 volumes normal human cells + 2 volumes of anti-hu rabbit serum.

Experiment 1 is the main test : 2, 3, 4, and 5 are contr

These mixtures were allowed to react at room temp ture for 30 minutes and were then washed three ti with normal saline, being thoroughly shaken at e washing to break up the cell clumps as much as poss To each mixture was now added one volume of P (all were thoroughly mixed and the cells were spun and the absorbed P (IV) serum was spun off and te in each case with sensitised sheep cells. The results w

(1) = Neg.
(2) = + + +
(3) = + + +
(4) = + + +
(5) = + +

DISCUSSION

The object of this study was to see whether principles implied in the paper by Coombs et al. (1 could be extended to a system other than the hu condition more closely resembled true rheumatoid ritis.

auer et al. (1941) describe the findings at dissection 26 cases of arthritis associated with psoriasis, and in there was typical rheumatoid arthritis. In 1 eptional case in a man who died at the age of 68 the ritis had been present for forty-four years but was fined to the distal interphalangeal joints and middle langes. The phalanges were destroyed, and the case a less extensive example of arthritis mutilans.

n all these cases the activity of the arthritis seems ave persisted, but in the present case, if the story may elieved, the arthropathy has been quiescent since 1930.

RELATION OF PSORIASIS AND ARTHRITIS

awson and Tyson (1938) reported that the incidence psoriasis in 1000 cases of rheumatoid arthritis was %, compared with 0·7% in 300 normal controls (Bauer al. 1941), a statistically significant difference. The n "psoriasis arthropica" describes this association is usually limited to a definite condition in which coincidental association is excluded:

1) Either psoriasis or arthritis may develop first, but the ditions should subsequently wax and wane in harmony.

2) The arthritis should affect the terminal interphalangeal nts; Bauer et al. (1941) go so far as to suggest the m should be limited to an arthritic condition affecting only terminal interphalangeal joints.

3) The psoriasis should be atypical and include pitting the nails of fingers and toes.

Dawson and Tyson challenge this view and describe cases of the associated conditions which all seem to of the same ætiology, though not strictly conforming those criteria. In 18 of their cases the arthritis and riasis fluctuated more or less together. Nail changes re present in most cases.

Comroe (1944) considers that the association of psoriasis d degenerative joint disease is purely a matter of chance, ough in such cases there is much greater likelihood of e terminal interphalangeal joints being affected and of ll-marked destructive joint changes. This is agreed Epstein (1939), whose study of 33 cases of psoriasis thropica showed that, when psoriasis coexisted, the int lesions tended to be more chronic and destructive d to persist until death. He describes the rapid provement in the joints when the psoriasis was treated.

DISCUSSION

The conclusion to be drawn from the cases of psoriasis thropica is that the joint lesion is usually typical rheumatoid arthritis, except that the terminal interalangeal joints are seriously affected (Poynton 1938, llmore 1946). Many cases are recorded, however, in hich the joint condition is not typical of rheumatoid thritis but shows some degree of arthritis mutilans ith absorption of the phalanges and metacarpals; e terminal phalanges tend to be spared. This is in cord with the general opinion that arthritis mutilans a rare variation of rheumatoid arthritis, but Comroe 944), Copeman (1948), and others say that it is more ely to occur when psoriasis is also present.

The typical features of the psoriasis are the pitting of e nails and the extensive generalised skin lesions which, cording to Epstein (1939), occur in 78·8% of such cases.

In the present case the arthritis and psoriasis seem to unrelated and have not waxed and waned in harmony, ut the unusual features of both conditions are those ore commonly found when the joint and skin lesions exist. It therefore seems probable that there is some mmon ætiological factor, and that the criteria suggested r "psoriasis arthropica" are too strict and would clude cases for which coincidence is not a satisfying planation.

The cause of the association of the conditions is nknown, but the possibility of a general circulatory abnormality is discussed by Garrod (1911) and Pemberton and Scull (1938). There is no indication of such abnormality in the present case, nor is there any evidence of a hereditary tendency, as Lane and Crawford (1937) and O'Donovan (1931) suggested—to the best of his knowledge the patient is the only sufferer from psoriasis or rheumatism in his family.

SUMMARY

A case is described in which arthritis mutilans was associated with psoriasis.

The joint condition preceded the psoriasis by eight years and, despite the extensive destruction of bone in hands and feet, it had apparently become quiescent before the skin disease started.

There have been no subsequent fluctuations in the two conditions.

Previous reports of psoriasis arthropica are reviewed, with special consideration of the variations from normal which are more common when the diseases are associated.

It seems probable that the skin and joint changes have a common ætiological factor.

I wish to thank the Agent-General for the Province of Ontario for permission to publish this case.

HEXAMETHONIUM BROMIDE

A. R. Hunter
M.D. Glasg., F.R.F.P.S., D.A.
VISITING ANÆSTHETIST, ROYAL INFIRMARY, MANCHESTER

The chemistry and pharmacology of the drugs of the methonium series have been fairly fully investigated in the experimental laboratory (Barlow and Ing 1948, Paton and Zaimis 1948a and b, 1949, Balaban et al. 1949), and some observations on the action of decamethonium and pentamethonium in man have been published (Organe et al. 1949, Organe 1949, Davies and Lewis 1949, Hewer et al. 1949, Arnold et al. 1949, Arnold and Rosenheim 1949). Lately another member of the series, hexamethonium, has become obtainable for clinical administration. It has proved quite useful; but, since it may have dangerous side-actions, I wish to draw attention to the precautions which must be taken when it is given.

Hexamethonium bromide has a dual action. First, it reduces both the more obvious depressant and the lesser known stimulant effect of decamethonium on the contraction of voluntary muscle. This reduction does not, however, amount to nullification and is least obvious in patients who have received large doses of decamethonium. Thus I have found that hexamethonium restores only the abdominal respiration and does not undo intercostal paralysis either in man or in the cat anæsthetised with pentobarbitone. Hexamethonium is therefore a much less complete antidote than neostigmine is to the muscle-paralysing action of curare. On the other hand, it is my

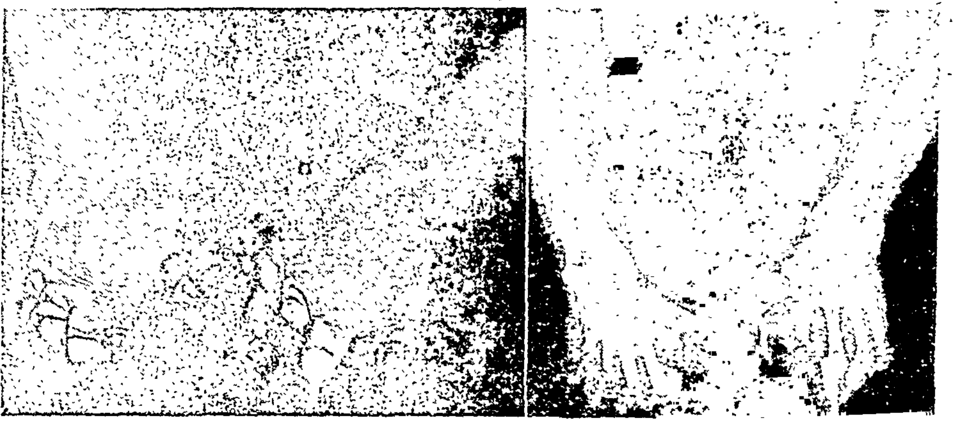

Fig. 1—Arthritis mutilans of hands. Note ununited fracture of left ulna.

forearm is well developed, and it is presumably because he has continued to use his hands that the rarefaction of wrist and metacarpals is limited.

Other Investigations.—Erythrocyte-sedimentation rate normal. Wassermann reaction and Kahn test negative. Blood-count: Hb 126% (Haldane); white cells 8000 per c.mm. (neutrophils 62%, lymphocytes 28%, monocytes 7%, eosinophils 2%, basophils 1%). Serum-phosphorus 4·2 mg. and serum-calcium 12·2 mg. per 100 ml.

Comment.—The patient had not been under medical supervision, so the history was only obtainable from him and the evidence of medical boards. From these sources the following facts emerge:

(1) In 1921 there was no abnormality of hands or feet and no skin disease.

(2) The arthritis lasted for about five years, during which time there was no psoriasis. This condition appears to the patient to have been quiescent since 1930, by which time his fingers had shortened to mere bags of useless flesh, without any pain or stiffness, but retaining normal skin sensibility. The course of the disease was unaffected by the simple treatment used, but even during the active stage he continued working, though with some difficulty and discomfort.

(3) The psoriasis did not start until about two years after the arthritis seemed to be quiescent.

(4) There is no evidence of any related fluctuations in the joint and skin conditions.

ARTHRITIS MUTILANS

Arthritis mutilans is generally considered to be an unusual variant of rheumatoid arthritis (Copeman 1948), but in the present case there are some differences. Typically, rheumatoid arthritis starts in the proximal interphalangeal joints of hands and feet and spreads centripetally to involve carpus and tarsus, wrist and ankle, and later other joints. Osteoporosis and destruction of the joint cartilage are followed by deformities and subluxations at the joints and finally by fibrous or even bony ankylosis. Kerley (19 also emphasises the bony ankylosis and the frequent destruction of the joints of the carpus and tarsus.

It is not known in which joints the arthritis originated in the present case, but the condition has remained localised, and there has been considerable destruction of bone, especially in the middle phalanges and distal interphalangeal joints. There is no sign of fibrous or bony ankylosis, and the carpus and tarsus are only slightly affected.

Cohen (1938) described a similar condition which had begun when the patient was a girl of 6 years and was still progressive at the age of 44; the metacarpals and phalanges of the hands were seriously involved, but the metatarsals were relatively unaffected. Radiography showed advanced changes in the distal interphalangeal joints of hands and feet, and the process had apparently attacked the phalanges in turn, taking 5–6 years to complete absorption of one bone . . . "slowly the bones of the hands seemed to melt away, leaving the soft structures unaltered." In this case, too, the soft tissues were extensible. Cohen suggested that the periosteum might assume some excessive resorpti function.

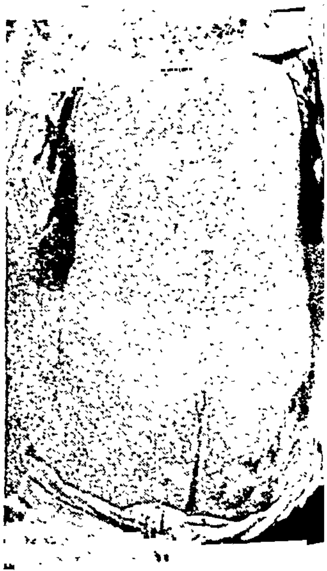

Fig. 3—Psoriasis of trunk and buttocks.

Marie and Léri (1913) described a case of *la main lorgnette*, which seems to have been a similar conditi In the hands and feet the long bones were larg destroyed, the soft tissues were too long for the phalan and the skin was loose and wrinkled. This condi resembled arthritis mutilans rather t rheumatoid arthritis, but the other jo of the limbs and spine were almost an losed by chronic rheumatoid arthritis.

Arthritis mutilans is commoner in conditions associated with psori (Copeman 1948), though in most of cases the joint lesion is almost typic rheumatoid arthritis. Such cases l been described by Shlionsky and B (1936), Schumaher and Lauter (1 Scholl (1925), and others. In the ca Shlionsky and Blake there was l destruction of the middle and d phalanges, whose joints seem to l been partly ankylosed, but the re of the metacarpophalangeal joints sho bone absorption, tapering, and subluxa

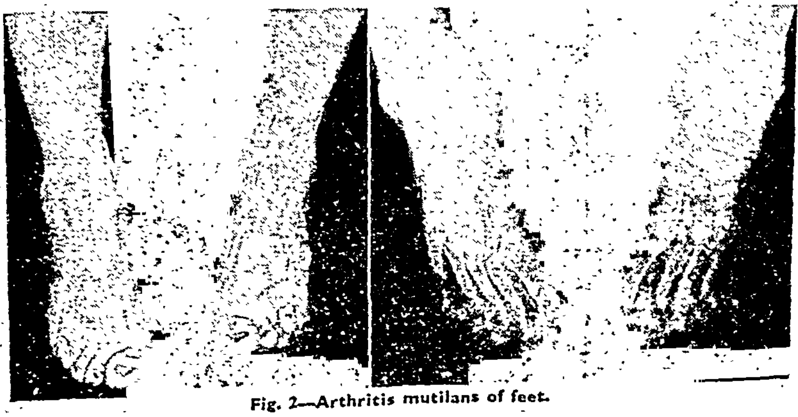

Fig. 2—Arthritis mutilans of feet.

The accompanying table shows the percentage fall in tolic blood-pressure after different doses of penta- thonium iodide. The percentage fall in systolic blood- ssure was calculated from the blood-pressure less n 5 minutes before and within 10 minutes after the ninistration of pentamethonium iodide. It will be preciated that the effect of this drug cannot equately be expressed by numerical blood-pressure dings.

The hypotension usually lasts about 15 minutes, after ich the blood-pressure slowly recovers, but in some es hypotension may last as long as an hour. The od-pressure seems to respond almost immediately to ravenous injection of ephedrine or 'Methedrine' in usual therapeutic doses.

OTHER EFFECTS

Besides its effects on the blood-pressure, penta- thonium iodide also dilates the pupil and relaxes the scles. The relaxation of the muscles is unlike that ained with curare and is more akin to the reduction muscle tone which occurs with mephenesin ('Mya- in'). Respiration may be irregular and inadequate, is easily controlled by manual compression of the ervoir bag. So long as the respirations remain con- lled or quiet, good relaxation obtains; as soon as the ient coughs or takes a deep inspiration the relaxation appears and generalised rigidity comes on, passing off soon as respiration is again brought under control. ch falls in blood-pressure and such respiratory effects y be extremely dangerous if the anæsthetist is not pared for them, and it is thought wise to draw atten- n to these side-effects of pentamethonium iodide which nder it unsuitable for clinical use as an antidote to camethonium iodide.

SUMMARY

In the anæsthetised patient pentamethonium iodide in ses as small as 10 mg. produces a profound fall in ood-pressure, even if the horizontal or head-down sition is maintained.

Effects on respiration and muscle tone are produced by ntamethonium iodide, and these may increase the nger of an unsuspected fall in blood-pressure.

Pentamethonium iodide should only be used as an tidote to decamethonium iodide with the utmost cumspection.

ECAMETHONIUM IODIDE AS A MUSCLE RELAXANT IN ABDOMINAL SURGERY

A. J. GRAY
M.B. Camb., D.A.
NIOR ANÆSTHETIST, PRESTON AND CHORLEY GROUP OF HOSPITALS

THE use of the decane member of the bistrimethyl- nmonium diiodide series of drugs (decamethonium dide, or 'C10') as a muscle relaxant in man has been escribed by Organe et al. (1949), and as an adjunct to eneral anæsthesia by Hewer et al. (1949). Its advantages clinical use over curarine (*d*-tubocurarine chloride) e claimed to be absence or diminution of histamine eration (Macintosh, F. C. quoted by Organe et al. 1949), d better minute-to-minute controllability of its effects ecause of its quicker detoxication. Its chief disadvan- ge is said to be the absence of a suitable antidote; entamethonium iodide ('C5') in many, though not ll, cases nullifies its relaxant effect, but also produces, mong other results, a profound fall in blood-pressure hich may endanger the patient's life (Hewer et al. 1949). Iexamethonium iodide ('C6'), in cats and rabbits, is said to be slightly *less* potent than pentamethonium as an antidote to decamethonium and *more* active in paralysing autonomic ganglia; but according to A. R. Hunter (personal communication) the reverse is true in man. In any case, hexamethonium is not entirely satisfactory as an antidote to decamethonium.

After these first reports had appeared, decamethonium iodide was tried in this hospital in a series of cases, all major abdominal sections. It was found to be satisfactory, with reservations, in nearly all cases. It was finally abandoned, however, and a reversion made to curarine because of the unpredictable occurrence, in a small proportion of cases, of a serious complication—delayed detoxication—a typical example of which is described below.

METHOD OF USE

Decamethonium iodide was used as an adjunct to thiopentone and endotracheal gas-and-oxygen, because this method of general anæsthesia had been eminently satisfactory when coupled with intravenous curarine.

Premedication consisted of morphine gr. $^{1}/_{6}$ and atropine gr. $^{1}/_{100}$ in adolescents and old patients; 'Omnopon' gr. $^{1}/_{3}$ and hyoscine gr. $^{1}/_{150}$ in the medium age-groups (18–55 years).

In the anæsthetic room a test dose of 0·5 ml. (1 mg.) of decamethonium was given intravenously, followed by a "safety pause" of 2 minutes for any undue effect to be observed. If all was well a further 1–1·5 ml. (2–3 mg.) was then given, the amount depending on the patient's physique and the site of the operation, followed immediately through the same needle by up to, but not more than, 10 ml. (0·5 g.) of 5% thiopentone. With the aid of a laryngoscope, direct intubation was then performed, and the tube connected directly, by the appropriate connections, to a standard Boyle's machine delivering 75% gas and 25% oxygen. The expiratory valve was kept shut, or nearly so, so that an element of insufflation was introduced. (With this technique the width of the glottal opening, and hence, provided the patient is "settled," the tone of the body musculature, can readily be estimated by observing the degree of distension of the re-breathing bag, since the surplus gases have to find their way out between the cords and the outside of the tube.)

The patient was then wheeled into the theatre and placed on the table. During the operation further doses of 0·5–1 ml. (1–2 mg.) of decamethonium iodide were given when relaxation appeared inadequate, as evidenced by obvious tightness of the abdominal wall or distension of the re-breathing bag. Signs that anæsthesia was returning to stage II (Guedel classification), were taken to be an indication for minute doses (0·5 ml.) of 5% thiopentone or sometimes latterly by 50 mg. doses of intravenous pethidine on the lines suggested by Mushin and Rendell-Baker (1949). In no case, with or without pethidine, was the total dose of 5% thiopentone more than 15 ml., and as experience was gained in the technique less and less was found to be necessary. Many cases were adequately controlled by their initial dose of 7–8 ml. (0·35–0·4 g.) alone.

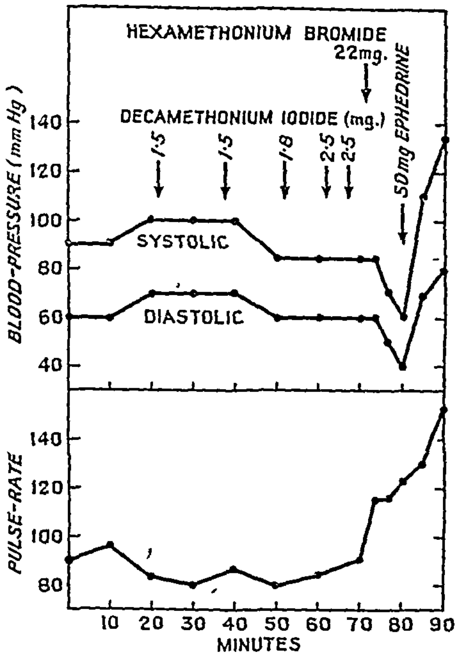
The average dosages used for different operations were as follows.

Site of operation	No. of cases	Average dose	
		Decamethonium iodide (mg.)	Thiopentone (ml. of 5%)
Appendix	36	5·0	9·5
Stomach	47	13·0	10·5
Rectum and large bowel	23	8·5	8·3
Gall-bladder	24	11·5	8·9
Uterus and appendages	3	6·4	9·4
Exp. laparotomy	13	7·5	10·4

It will be seen that the operations which last longest and require the deepest relaxation—i.e., gastric operations—received the highest average dose, and that the dosages for other types of operation were based on the same considerations.

There was one death related to anæsthesia in this series: a woman, aged 60, with hyperpiesia and myoimpression that hexamethonium is more effective than pentamethonium, since in the course of 15 administrations of 25–50 mg. of hexamethonium I have always observed some increase in the depth of respiration in the anæsthetised patient. This experience compares favourably with that of Hewer et al. (1949) with pentamethonium under similar conditions; they found that the drug failed on 6 out of 8 occasions, and in 2 of my own cases pentamethonium was given with a disappointing result. This short study of the antidotal action of hexamethonium suggests that it can be relied on to improve respiratory exchange, when it has been depressed by decamethonium, sufficiently to prevent patients from dying of anoxia, though it will by no means completely restore all muscle power.

The other outstanding action of hexamethonium is the paralysis of the autonomic ganglia which it is liable to produce. Pentamethonium also has this action (Arnold and Rosenheim 1949, Arnold et al. 1949, Hewer et al. 1949) though it is not quite so dangerous in this respect (Paton and Zaimis 1949). It is thus hardly surprising that when I began to give hexamethonium to patients I always observed some fall in blood-pressure. In the very first case it seemed that the ensuing hypotension might be severe enough to be fatal (see figure), but the injection of ephedrine quickly restored the circulation to normal. In view of this and several other less startling experiences I now give 30–50 mg. of ephedrine or 10–20 mg. of 'Methedrine' with each dose of hexamethonium. I have observed an analogous disturbance to this in cats, but in them evidence of paralysis of the autonomic ganglia appears only if the cat's circulation is already embarrassed for some other reason. Thus, when hexamethonium is given to a cat anæsthetised with pentobarbitone but otherwise normal, the blood-pressure does not change; but, if the cat is anoxic owing to respiratory depression produced by decamethonium, hexamethonium will cause an extreme fall in blood-pressure, which, however, will recover if the lack of oxygen is corrected by artificial respiration. If it is accepted that this observation is transferable to man, the importance of avoiding the use of hexamethonium until the oxygenation of the blood has been restored by artificial ventilation should need no further emphasis.



Effect of hexamethonium bromide (given after decamethonium iodide) on blood-pressure and pulse-rate, countered by giving ephedrine.

SUMMARY

Hexamethonium bromide is a partial antidote to the muscular paralysis produced by decamethonium iodide. It is probably sufficiently effective to be of value in clinical anæsthesia.

Hexamethonium bromide, however, also paralyses the autonomic nervous system and can thus cause a serious fall in blood-pressure. It should therefore never be given alone but should always be accompanied by a vasopressor.

PENTAMETHONIUM IODIDE IN ANÆSTHESIA

M. H. Armstrong Davison
M.B.E., M.D. Durh., D.A.
CLINICAL ASSOCIATE, DEPARTMENT OF ANÆSTHETICS, ROYAL VICTORIA INFIRMARY, NEWCASTLE UPON TYNE

Pentamethonium iodide, also known as 'C5' and sold under the proprietary name of 'Antilusin' (Allen & Hanburys), was introduced to the medical profession as the antidote to decamethonium iodide, a synthetic muscle relaxant used to a considerable extent in anæsthesia whose action is said not to be reversed by neostigmine.

Organe et al. (1949) first described this action of pentamethonium iodide and recommended a dose of 10 mg. for each mg. of decamethonium iodide. Attention has since been drawn to the effect of pentamethonium iodide on the blood-pressure. Arnold and Rosenheim (1949) and Arnold et al. (1949) have shown that, in the conscious hypertensive person, pentamethonium iodide in doses up to 100 mg. causes a considerable fall in blood-pressure, whereas in the conscious normal person the blood-pressure does not fall so long as a horizontal position is maintained, but the subject's blood-pressure becomes extremely posture-sensitive and remains so for at least an hour.

EFFECT ON BLOOD-PRESSURE DURING ANÆSTHESIA

Pentamethonium iodide has been used in hypertensive and normal people in the Royal Victoria Infirmary, Newcastle upon Tyne, as an adjuvant to anæsthesia, to reduce blood-pressure and therefore hæmorrhage during such operations as sympathectomy, Millin's prostatectomy, and radical mastectomy. Anæsthesia was induced by inhalation of various agents, including nitrous oxide, ether, cyclopropane, and chloroform. In all the cases there was a severe fall of blood-pressure in $2^{1}/_{2}$–5 minutes. The systolic pressure always fell to 80 mm. Hg or lower (lowest 50 mm. *Hg*). This effect was obtained with the patient horizontal or head down and with doses as small as 10 mg.

DIMERCAPROL (BAL) IN ACUTE ANTIMONY DERMATITIS

D. A. W. Rittey
M.B. Edin.
EDICAL OFFICER, SOUTHERN RHODESIA MEDICAL SERVICE

Fakhry[1] noted in 1929 that there were two types of rmatitis following the administration of antimony: e a fairly common mild papular eruption that required treatment; the other a scaly type which was rare. e described a case of the scaly type in a patient under atment with stibophen who had previously had two jections of tartar emetic a year; when the rash appeared e treatment was discontinued. In this instance Fakhry ve 10 ml. of a 10% solution of sodium thiosulphate travenously on two successive days, with good results.

Local papular or vesicopapular eruptions, usually nfined to a limited area of skin, have also been escribed; those resembling herpes often affect the istribution area of the accessory nerve. Alves and lair[2] and Ritchken and Cantor[3] have described such ases following both orthodox and intensive treatment ith intravenous antimony. A branny desquamation f the skin, particularly of the hands, is a common sequel all forms of antimony therapy. A true exfoliative ermatitis, such as developed in the following case, is ertainly rare.

CASE-RECORD

An African youth, aged about 18, was admitted to a native linic with hæmaturia. Eggs of *Schistosoma hæmatobium* were ound in his urine. Beginning on May 13, 1948, he was given ml. of a 6% solution of lithium antimony thiomalate intra-muscularly on two successive days. On the third day a fine rythematous rash appeared and by the next day this had ecome very severe and extensive. The patient had previously een treated at a mission hospital and had been given twelve ntramuscular injections of an antimony preparation, most kely either stibophen or antimony thiomalate, soon after hich a rash had appeared, which had ultimately disappeared ithout treatment. There was no history of venereal disease r of treatment with arsenicals, and none of any previous llergic manifestations in either the patient or his parents. There was no evidence of contact with any substance or drug other than the medicine) likely to have precipitated a kin rash.

On examination the patient complained of severe skin rritation and looked ill. He had nausea but no vomiting. The tip of his tongue looked red and raw. The eyes were suffused and the conjunctivæ injected. There was no enlargement of the liver or spleen and no other abdominal signs or symptoms. The urine contained a few red cells and hyaline casts and eggs of *S. hæmatobium*.

The skin was affected by a severe exfoliative dermatitis with bullous eruptions, severe excoriations in some areas, and a raw oozing surface in others. Anteriorly the areas affected included the lower abdomen and the front of the right thigh to the knee. The mammary area on both sides and the axillæ were affected, as were also the medial aspect of the left arm extending into the axilla, and the right deltoid area and wrist. Posteriorly the oozing surface extended from the axillæ on to the back. The natal cleft and neighbouring parts of the buttocks and the perineum were excoriated and fissured. A similar condition was found over both popliteal fossæ. There were also extensive areas of desquamation over both scapulæ, the elbows, and in a " waist band " 4 in. wide across the lumbar region.

Treatment.—On May 17, four days after his first antimony injection, the patient was transferred to the main clinic at Concession, where treatment with dimercaprol was started immediately. No local treatment of the lesions was instituted except for dry dressings to protect the oozing surfaces. On the first day 2 ml. of dimercaprol was given intramuscularly four-hourly for four doses. On the next three days 2 ml. was given twice daily, morning and evening. On the fifth and sixth days 2 ml. was given once each day.

Progress.—There was no evidence of intolerance to dimercaprol. By the fourth day of treatment the excoriations and fissurings had healed, and by the sixth day all lesions had disappeared.

COMMENT

This case is an instance of intolerance to a relatively small dose of antimony, and the first course of treatment seems to have sensitised the patient to the metal. The very extensive lesions cleared in a truly dramatic way, and it was difficult to believe that, six days earlier, large areas of his skin were raw oozing surfaces with fissures and excoriations. In addition to the skin eruption, other symptoms and signs of intoxication with antimony were present—nausea, and suffused and injected conjunctivæ.

I am grateful to Dr. R. M. Morris, O.B.E., secretary for health, Southern Rhodesia, for permission to publish this case.

HEREDITARY HÆMORRHAGIC TELANGIECTASIA

T. Cochrane
M.D., B.Sc. Glasg.
SECOND ASSISTANT PHYSICIAN

G. Leslie
M.D. Glasg.
CLINICAL ASSISTANT

DEPARTMENT OF DERMATOLOGY, ROYAL INFIRMARY, GLASGOW

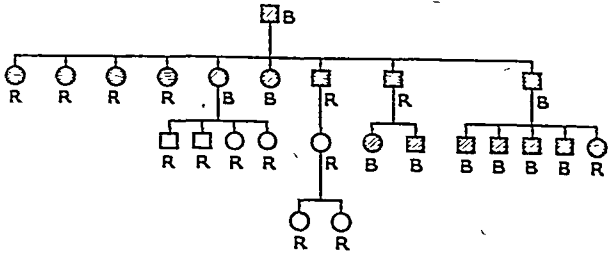
Hereditary hæmorrhagic telangiectasia is a well-recognised but rare condition. The characteristic lesions are telangiectases and angiomas which develop slowly on the face and body after puberty. Severe anæmia may result from hæmorrhage, most commonly recurrent epistaxis, but severe melæna and hæmoptysis have been described.

The following case is typical but illustrates an unusual form of heredity and an excellent response of the dermal lesions to treatment with contact X rays.

CASE-RECORD

A woman, aged 49, reported at the outpatient department, Royal Infirmary, Glasgow, with " multiple bleeding moles." As a child and young woman she had had epistaxis almost daily. After the age of 30 these attacks had gradually become less frequent, but two years ago the patient had had such a severe epistaxis that blood-transfusion was necessary. During the past eighteen months she had had repeated hæmorrhages from angiomas on the face and scalp. These angiomas had first appeared when she was 10 years of age. Since then they had gradually increased in number and size, and bled on the slightest trauma. Up to the age of 7 the patient had had numerous generalised convulsions. Since then they had disappeared, and her general health had been excellent except for the frequent hæmorrhages.

On examination the patient was a well-nourished healthy dark-haired middle-aged woman with multiple vascular nævi



Hereditary hæmorrhagic telangiectasia: square symbols, males; circular symbols, females; hatched symbols, angiomas and hæmorrhages; stippled symbols, hæmorrhages but not angiomas; B, black-haired; R, red-haired.

cardial degeneration collapsed and died from heart-failure during the first hour after completion of a synchronous combined abdominoperineal resection of the rectum. Undoubtedly a contributory factor was the patient's failure to regain normal depth of respiration. She had been given 7 ml. of 5% thiopentone, and a total of 2 ml. (4 mg.) of decamethonium iodide, the last mg. of this 20 minutes before the end of the operation.

RESULTS

Satisfactory operating conditions were produced in all cases, though inevitably in several instances the surgeon was held up momentarily while a supplementary injection was given and was taking effect. In operations lasting sufficiently long the patient became "tight" under stimulation, and required further decamethonium iodide about 20–30 minutes after the previous effective dose. The drug was therefore found particularly satisfactory in such procedures as straightforward appendicectomy, where the initial dose given in the anæsthetic room lasted long enough for the operation to be done and the peritoneum closed but had almost completely lost its effect by the time the patient returned to the ward.

DISADVANTAGES COMPARED WITH CURARINE

The patient's subjective sensations during the "safety pause" after the preliminary injection of 0·5 ml. (1 mg.) were considerably more unpleasant than when 0·5 ml. (5 mg.) of curarine was given. Nearly all patients, except those strongly sedated by their premedication, swallowed, moaned, and moved their head from side to side during this wait. That this difference is not entirely due to the earlier onset of the effect of decamethonium may be shown by waiting longer than 2 minutes after giving 5 mg. of curarine, when no such trouble is caused. Possibly it is a consequence of the less gradual loss of muscular power which is induced by decamethonium.

At laryngoscopy the cords were nearly always (95% of cases) found in spasm, as contrasted with equivalent doses of curarine where the cords are open in about half the cases. The well-lubricated tip of the endotracheal tube, however, provided the bevel was accurately aligned, was in all cases slipped through the closed glottis without trauma or undue difficulty. Between a third and half of the cases developed apnœa after intubation, and this lasted until the towel-clips were vigorously applied or the skin incision made. This high incidence of laryngeal spasm and postintubation reflex apnœa, compared with that after the use of curarine, is presumably connected with the fact that curare is a stimulant to the respiratory centre, antagonising thiopentone in this respect (Gray 1948), whereas decamethonium has no such effect.

The usual technique of administering additional doses of curarine, thiopentone, or pethidine during operations was, and is, by means of a syringe strapped to the neck, attached to a hypodermic needle (gauge no. 17) inserted and left in one or other external jugular vein. If this technique is attempted when using decamethonium, the minute clot which inevitably blocks the needle after a time is extraordinarily tenacious and quite "unshiftable" by ordinary thumb pressure, so either a larger needle or multiple punctures must be used. A Gordh needle was not obtainable for trial.

The margin between the dose required to produce adequate relaxation and that causing apnœa from muscular failure (as distinct from reflex apnœa mentioned above) is smaller than with curarine, being often less than 0·5 ml. (1 mg.), but no serious trouble arose from this factor. Assisted respiration keeps the patient in good condition until spontaneous respiration returns —in this series always less than 7 minutes.

In 4 cases in this series return of reasonable muscle tone, and hence of adequate respiratory exchange, was delayed beyond the end of the operation. The most serious of these cases, described below (by kind permission of Mr. R. M. Corbet, whose patient this was) was so disturbing that the use of the drug was abandoned except in isolated instances.

CASE-HISTORY

A married woman, aged 46, complained of vaginal bleeding for 6 weeks. She was a very stout woman, with no definite local signs apart from slight tenderness on the left side of the abdomen. Her general condition was fair (she had stopped bleeding 2 weeks before). Blood-pressure [illegible] mm. Hg; Hb 85%. It was decided to examine her under anæsthesia and operate if indicated.

Under anæsthesia it was possible to feel an enlarged uterus with a mass on the right. The abdomen was opened, and a uterus with multiple fibroids, including a pedunculated one (the mass), and both ovaries were removed. There was minimal bleeding and the entire procedure took 1 hour 25 minutes.

The Anæsthetic.—Premedication: omnopon gr. 1/3, hyoscine gr. 1/150. The patient was given 0·5 ml. (1 mg.) of decamethonium iodide, and the relaxation so produced after 2 minutes being normal, a further 1 ml. (2 mg.) of decamethonium plus 10 ml. of 5% thiopentone was injected. She was intubated, the endotracheal tube was connected to the usual flow of gas-and-oxygen, and she was taken into the theatre for examination in the lithotomy position. She was later placed in steep Trendelenburg position for the actual operation, at the start of which a further 1 ml. (2 mg.) of decamethonium was given. Because of the steepness of the Trendelenburg position, and the stoutness of the patient, respiration had to be assisted by synchronised squeezing of the re-breathing bag. During the operation two further doses of decamethonium were given, one of 1 ml. (2 mg.) and the last of 0·5 ml. (1 mg.). A total of 4 ml. (8 mg.) was thus given, the last dose of which was half an hour before the abdominal wall was closed. At no time was there apnœa.

Progress.—At the end of the operation the patient's respiration was slow, shallow, and jerky, being chiefly intercostal rather than diaphragmatic (feminine type). When the endotracheal tube was disconnected from the Boyle's machine and removed, the patient became cyanosed, though her pulse remained of good volume. A 1 ml. dose of pentamethonium iodide was "eased" into the circulation over a period of 2 minutes; the result was a gross deterioration in the volume of the pulse, which became undetectable at the wrist, without any significant increase in respiratory exchange. She was at once given 30 mg. of methyl-amphetamine ('Methedrine') intravenously, but her condition still remaining poor she was re-intubated and the tube was connected to a supply of pure oxygen, under slight pressure, from a Walton machine. There was an immediate striking improvement in both colour and pulse and she was accordingly left in the theatre under this treatment.

An hour later, despite her good colour and pulse, and the relatively small dose of thiopentone originally administered, her pupils were still widely dilated, and her reflexes were sluggish—for example, there was no response to firm pressure over the supraorbital nerve. The volume of respiration was, however, slowly returning though still far from normal.

Not until 1½ hours later still (3 hours after the last dose of decamethonium) was it thought reasonable to "wean" the patient from the pure oxygen. She stood this well and after another hour her reflexes and consciousness were returning.

Her subsequent convalescence was uneventful and she was discharged 3 weeks after the operation fit and well. This showed either remarkable constitutional resistance or unusual good luck, for the combination of prolonged shallow respiration, inhalation of pure oxygen, and temporary but severe fall in blood-pressure made the development of postoperative pulmonary complications extremely likely.

In view of the fact that this patient had (*a*) responded normally to a test dose of 0·5 ml. (1 mg.) of decamethonium; (*b*) required, without being unduly affected at the time by it, a further 3·5 ml. (7 mg.) of decamethonium to permit the operation to be satisfactorily performed, and (*c*) failed to regain her normal depth of respiration until 4 hours after the last dose of decamethonium despite the exhibition of the recommended antidote e equal and reacted normally, optic fundi showed slight rring of each disc but no papillœdema. There was no argement or tenderness of any of the salivary glands and evidence of middle-ear disease; the respiratory system wed no abnormality. The cardiac borders were normal, d the heart sounds were pure. The pulse was regular and good quality, rate 58 per min. Blood-pressure 105/80 mm. . There was no hepatic or splenic enlargement. The urine s normal. A blood-count showed Hb 95%, red cells 00,000 and white cells 6800 per c.mm. (lymphocytes 40%). ere was a typical epididymo-orchitis on the right side, with rm tender swelling and obliteration of the natural sulcus. ere was no urethral discharge, inguinal adenitis, or argement of the prostate.

Lumbar puncture on admission produced transparent C.S.F. der slightly increased pressure and containing 180 cells c.mm. (practically all lymphocytes), protein 80 mg., orides 740 mg., and sugar 60 mg. per 100 ml. No organisms re found in this or subsequent specimens.

Recovery was progressive and uneventful. The patient's nperature was normal two days after admission and nained so; his headache steadily diminished and had npletely disappeared after six days, neck stiffness was sent for four days, bradycardia was evident for the first rteen days in hospital, the pulse-rate varying between and 64 per min.; thereafter the rate gradually increased, ing 70–80 before the patient was discharged. The changes the C.S.F. are shown in the accompanying table. The

CHANGES IN CEREBROSPINAL FLUID

Date	Cells (per c.mm.)	Protein (*mg. per* 100 ml.)	Sugar (*mg. per* 100 ml.)	Chlorides (*mg. per* 100 ml.)

olloidal gold test showed a moderate mid-zone curve. The lood Wassermann and Kahn tests and C.S.F. Wassermann st were all negative. The Schüffner reaction and Paul-unnell test were also negative. The patient was discharged ell on June 1, 1949.

DISCUSSION

The difficulties in diagnosing mumps meningitis in he absence of parotitis are obvious. Eberlein and ynxwiler (1947) emphasise the problem of differentiating he condition from lymphocytic choriomeningitis, poliomyelitis, and encephalitis due to other viruses. They onsider that the C.S.F. findings in mumps are characteristic, with commonly 200–400 cells per c.mm., but he count may be as high as 3000. Protein is usually normal, chlorides and sugar show little deviation, and he colloidal gold curve is seldom abnormal. Bang and Bang (1943) draw a definite distinction between mumps neningitis and mumps meningo-encephalitis, pointing ut that meningitis runs a benign course and that neningo-encephalitis is a rare and more dangerous complication which may be associated with various types of paresis, including hemiplegia and monoplegia, and with acute ataxia and convulsions.

In the present case the combination of meningitis with orchitis was strongly suggestive of mumps. The diagnosis was made practically certain by the patient's statement that he had not previously had mumps, and by his son's typical attack of mumps starting 14 days before the patient's first symptoms.

An interesting feature of the present case was the bradycardia. A slow pulse and absence of vomiting are considered by some French clinicians to be points of diagnostic importance in mumps meningitis, but Coe (1945) and Harris and Bethell (1938) did not find them in their cases.

The occurrence of cases such as the one described here suggests that the classification "benign lymphocytic meningitis" probably includes a proportion of cases due to infection with the virus of mumps. It also demonstrates the unsuitability of epidemic parotitis as a synonym for mumps.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Fits and Fainting

ON Feb. 2 the section of neurology, with Mr. JULIAN TAYLOR, the president, in the chair, discussed Fits and Fainting.

Sir CHARLES SYMONDS, remarking that the symptom common to fits and faints was loss of consciousness, defined a fit as being a disorder of function which was in onset local in origin and therefore one would expect the symptoms to show variety depending on the part of the brain in which the impulse arose. There were many varieties of epileptic attack in which no local origin was apparent; the speed of discharge was so rapid that involvement at once became general. In a faint there seemed to be an order of susceptibility. The retina and areas concerned with postural equilibrium failed early. In a faint, if the onset of anoxæmia was not too abrupt, there was an order of loss of function which was characteristic: dimness of vision, loss of balance, unconsciousness. In certain cases, however, the loss of consciousness might be abrupt. Also it might be caused by emotion, and this might lead to confusion of a fit and a faint, which became even more likely where convulsive movement occurred in a faint. In a series of 362 cases of fainting, convulsions were noted in 7%. When together with loss of consciousness there was loss of balance, it could be taken that the attack was a faint; if there was loss of consciousness without falling, it was a fit. Ventricular standstill might also cause convulsions if it persisted for 10–20 seconds. Postural hypotension, producing pallor, unconsciousness and falling, might also be confused with epilepsy. Discussing epileptic attacks originating in the visceral centres, he said that pallor, nausea and palpitation and dizziness might usher in a complete epileptic attack or be the only manifestations of it. Vasovagal attacks were, he believed, very rare, and they were not to be confused with cerebral anxiety states. Gowers applied the term for attacks originating in the medullary centres and associated with epigastric discomfort, respiratory distress, coldness, pallor, and a sense of impending death. Later Lewis used the term for fainting, but vasovagal attacks were not faints or fits, in the ordinary sense, although they might be confused with them if seen separately. Fainting very rarely occurred except in the erect posture. If an attack took place after long standing or after emotional disturbance, it might be assumed to be a faint. But epileptic attacks might be due to a number of causes, of which emotion was one and the malaise preceding illness another. Sir Charles considered that urinary incontinence during unconsciousness was characteristic of epilepsy; though it might also occur with a faint if the bladder was over-full, but not otherwise. A spell of yawning was often a precursor of an epileptic attack. He stressed that excessive liability to fainting in childhood might be followed by excessive liability to epilepsy later; and some people exchanged migraine for epilepsy. Anyone might have a fit or a faint for sufficient cause.

on the trunk, hands, scalp, and face. The nævi varied in size from pin-point to several millimetres in diameter. The two largest were situated on the vertex. The angiomas in all areas were associated with definite telangiectases. On the mucosa of the hard and soft palates and inside of the cheeks telangiectases were particularly conspicuous, and on the tongue were multiple small nævi entangled in a mesh of telangiectases.

Examination of Blood.—Red cells 4,060,000 and white cells 4800 per c.mm. (differential count and film normal), platelets 300,000 per c.mm., Hb 92% (14·9 g. per 100 ml. = 100%). Bleeding-time 3 min., coagulation-time $5^1/_2$ min., and prothrombin-time 45 sec. (control 32 sec.). Capillary fragility normal. Blood-pressure 120/80 mm. Hg. Investigation of the other systems revealed no abnormality.

Family History (see figure).—The patient's grandfather was black-haired, had angiomas on both hands, and suffered from repeated epistaxis. Four aunts, all red-headed, had had repeated epistaxis but no angiomas or telangiectases. The first of these aunts died from a postoperative hæmorrhage; the second and third died from hæmorrhage when still children. The fourth was still living and having repeated epistaxis but had no visible signs of the disease. Two other aunts, black-haired, had angiomas and telangiectases of face and hands and a history of various types of hæmorrhage. One of these aunts died at the age of 72 from an unconnected disease. The other was still alive and had large bleeding angiomas on both hands. Two sons and two daughters of the dead aunt were completely free from the disease. One uncle of the patient died from postoperative hæmorrhage; during life he had had repeated epistaxis but no angiomas or telangiectases. His daughter and her children were completely free from stigmata. This uncle and his daughter had red hair. A second uncle had multiple nævi on the face and scalp and in the mouth. His four sons had vascular nævi on their faces and hands, and his one daughter suffered from repeated epistaxis but was otherwise free from stigmata of the disease. This uncle and his four sons had black hair, and his daughter had red. The patient's father, who had red hair, had had repeated epistaxis but no other evidence of the disease. The patient's brother, black-haired, had angiomas of the face and frequent hæmorrhages from these and his tongue.

Treatment.—The largest and most easily injured angiomas on the scalp and face were treated with the Philips contact-therapy machine; 750 r was given at 50 kV, 2 mA, 2 cm. skin target distance with no added filtration. Eighteen nævi were given contact X rays.

Progress.—Nine months after treatment many of the nævi have disappeared. There has been no further spontaneous hæmorrhage from those on the scalp or face and slight trauma does not produce bleeding from the two large angiomas on the vertex. These are now much less raised and the covering epithelium appears to be much thicker and stronger.

DISCUSSION

In the present family there seems to be two types of persons presenting different stages of hereditary hæmorrhagic telangiectasia: (1) red-haired members of the family who have either no signs or symptoms of the disease or else only repeated hæmorrhages; and (2) dark-haired members who present the typical text-book picture of repeated and varied forms of hæmorrhage, telangiectases, and multiple hæmangiomas scattered over the body.

Goldstein[1] described the condition as a hereditary hæmorrhagic dysplasia with normal cytological findings in the blood except for secondary anæmia. Penfold and Lipscomb,[2] however, reported a family in which the disease was associated with elliptical red cells. Examination of blood films did not reveal any abnormal red cells in the present case.

MacKee and Cipollaro[3] prefer to use radium for the treatment of angiomata, but in the present case it was decided to treat the lesions, which were widely scattered, with contact X rays. Andrews[4] is of the opinion that the best results are obtained with doses of 250 r through 2·5 mm. of aluminium and given at intervals of six weeks for from four to six doses. We, however, adopted the dosage we most often use in treating superficial angiomas, and the lesions responded well to the small dose of contact X rays.

We are indebted to Dr. George Harvey, physician to the department of dermatology, Royal Infirmary, Glasgow, for permission to publish this case.
